ABSTRACT: In this work a new curvilinear coordinate system is presented for the comprehensive description of polytopal rearrangements of *N*-coordinate compounds ($N = 4-7$) and systems containing an *N*-coordinate subunit. It is based on normal vibrational modes and a natural extension of the Cremer−Pople puckering coordinates (*J. Am. Chem. Soc.* **1975**, *97*, 1354) together with the Zou−Izotov−Cremer deformation coordinates (*J. Phys. Chem. A* **2011**, *115*, 8731) for ring structures to *N*-coordinate systems. We demonstrate that the new curvilinear coordinates are ideal reaction coordinates describing fluxional rearrangement pathways by revisiting the Berry pseudorotation and the lever mechanism in sulfur tetrafluoride, the Berry pseudorotation and two Muetterties' mechanisms in pentavalent compounds, the chimeric pseudorotation in iodine pentafluoride, Bailar and Ray-Dutt twists in hexacoordinate tris-chelates as well as the Bartell mechanism in iodine heptafluoride. The results of our study reveal that this dedicated curvilinear coordinate system can be applied to most coordination compounds opening new ways for the systematic modeling of fluxional processes.

CURVILINEAR COORDINATES
1. INTRODUCTION

Fluxional processes, in particular polytopal processes, have recently attracted attention caused by their potential to probe solvent−solute interactions[1−3] and to support self-healing processes.[4]

The term *polytopal rearrangement* describes a dynamic process that alters the positions of the vertices defined by the ligands in a coordination polyhedron; i.e., it "interconverts different or equivalent spatial arrangements of ligands about a central atom" as stated in the IUPAC Gold Book.[5−8] A well-known example for polytopal rearrangement found in most inorganic chemistry textbooks is the Berry pseudorotation of the PF_5 molecule.[9,10] Polytopal rearrangements being specific to coordination compounds are a subset of the broader class of *fluxionality*.[11−13] Many studies use "fluxionality",[14−16] "topomerization",[17] "stereomutation/enatiomerization",[13,17,18] "pseudorotation",[19−21] "permutational isomerization",[18,22] "polyhedral rearrangement/interconversion",[23,24] or "non-dissociative ligand exchange"[25] as a synonym for polytopal rearrangements.

Although a polytopal rearrrangement does not involve any ligand elimination and/or addition (i.e., no bond breaking and/or bond forming), it is of significant importance for chemists to understand the dynamics of such a process due to two reasons. (i) Fluxional flexibility can lead to more than one thermally accessible structure or to molecules with a dynamic structure, recently coined as molecules with a *quasistructure*.[26] (ii) Polytopal rearrangements affect the stereoselectivity and the reaction mechanism; therefore, they are critical for the reactivity and catalytic activity for many metal complexes.[27−34]

The tool extensively used by experimental chemists to determine molecular fluxionality is dynamic NMR spectroscopy.[13,35−38] On the basis of whether a polytopal rearrangement is either fast or slow compared to the NMR time scale,[39] its rate constant can be obtained by the Eyring equation.[12,40]

However, NMR spectroscopy is not able to provide us with information about the actual path that the atomic nuclei are tracing during a polytopal rearrangement. Therefore, we have to resort to quantum chemical calculations to model this path and verify the proposed mechanism(s) by calculating the activation energy.[41,42] On the one hand, often theory is guiding the experiment;[17,25] on the other hand, numerous mechanisms derived from experimental results await theoretical validation.[34]

One major obstacle in modeling polytopal rearrangements in coordination compounds is the lack of a generally applicable set of reaction coordinates tailored exclusively to distinctive *N*-coordinate geometries. Although some tricks (e.g., combining several bond angles[18] or dihedral angles[43]) could be employed

when driving the reaction complex into a desired reaction channel, these workarounds cannot achieve a systematic exploration of the configuration space of the N-coordinate motifs. However, it is of great necessity to determine all possible fluxional mechanisms for a specific geometry.

Noteworthy is the work related to polytopal rearrangement by Avnir, Alvarez, and co-workers who developed continuous symmetry measure (CSM) and continuous shape measure (CShM).[23,24,44−46] Their approach quantifies to what extent the geometry of a coordination compound matches the geometry of a reference compound with high symmetry or that of a regular polyhedron. By defining the "minimal distortion paths" for several polytopal rearrangement mechanisms, one can position a given coordination geometry onto the predefined minimal distortion paths.[23] After enumerating all relevant X-ray crystal structures with this approach, they observed a concentrated distribution of the geometries along the minimal distortion path, which they visualized as a "shape map". These results convincingly proved the existence of a polytopal rearrangement mechanism with numerous discrete structures. CSM and CShM measures offer a simplified way to describe and categorize the geometries of coordination compounds. However, one caveat is appropriate; the structural descriptors based on CSM/CShM will generally not span the complete configuration space of the N-coordinate motif and as such cannot serve as reaction coordinates used for practical calculations modeling polytopal rearrangement pathways.

Therefore, in this work, we adopted the conceptual approach of Cremer−Pople ring puckering coordinates[47] aiming at the development of a curvilinear coordinate system that provides appropriate reaction coordinates to (i) facilitate modeling polytopal rearrangements in N-coordinate molecules and (ii) present a simplified but comprehensive description of the conformational changes taking place during these rearrangements.

The paper is structured in the following way: First, the ring puckering and deformation coordinates are briefly reviewed in terms of their underlying rationale as the basis to define the N-coordinate reference system AB_n, its symmetry, configurational space, and molecular vibrations. Then, the curvilinear coordinate parameters for any N-coordinate geometry ($N = 4$−7) are derived from normal vibrational modes of the corresponding reference system. After the Computational Details section, nine different polytopal rearrangement mechanisms ranging from tetracoordinated to heptacoordinated compounds are revisited using the curvilinear coordinates derived in this work to demonstrate the general applicability of our new approach. The conclusions, along with perspectives on future work, are given in the last section.

2. METHODOLOGY

2.1. Retrospective on Cremer−Pople Ring Puckering and Deformation Coordinates.
The Cremer−Pople ring puckering coordinates proposed in 1975 have become a well-accepted standard tool to describe the out-of-plane conformational flexibility of ring structures in cyclic molecules.[47−53] It is based on the concept of partitioning the $(3N − 6)$-dimensional configuration space of an N-membered ring structure ("N-ring") into two subspaces where ring puckering and deformation motions take place, respectively.

Any N-ring has an $(N − 3)$-dimensional puckering space spanned by $N − 3$ basis conformations whose linear combinations are specified by ring puckering coordinates. The

z-component of the Cartesian coordinates for each ring atom z_j ($j = 1, 2, ..., N$) depicting the puckering conformation relative to an ideal planar form (mean ring plane) is connected to the puckering amplitude q_m and pseudorotation phase angle ϕ_m via the following formulas depending on the parity of N:[47,48]

$$z_j = \sqrt{\frac{2}{N}} \sum_{m=2}^{(N-1)/2} q_m \cos\left[\phi_m + \frac{2\pi m(j-1)}{N}\right] \qquad (N \text{ odd}) \tag{1}$$

$$z_j = \sqrt{\frac{2}{N}} \sum_{m=2}^{(N-2)/2} q_m \cos\left[\phi_m + \frac{2\pi m(j-1)}{N}\right] + \sqrt{\frac{1}{N}} q_{N/2}(-1)^{j-1} \qquad (N \text{ even}) \tag{2}$$

where a pseudorotation cycle only starts from the five-membered ring ($N − 3 = 2$) and the puckering coordinate pair (q_2, ϕ_2) is used to describe the motion in the puckering subspace. Puckering starts from the four-membered ring ($N − 3 = 1$) with the puckering amplitude q_2.

The in-plane deformations of the N-ring take place in a $(2N − 3)$-dimensional subspace complementing the $(N − 3)$ out-of-plane motions to $(3N − 6)$ coordinates. In recent work, we derived the ring deformation coordinates (RDC) as the complement to Cremer−Pople puckering coordinates rendering a whole picture of the ring configuration with curvilinear coordinates.[54−56] The definition of RDCs relies on further partitioning of the $(2N − 3)$-dimensional deformation space into (1) a one-dimensional ring breathing mode subspace, determined by the breathing radius R and (2) $N − 2$ two-dimensional pseudorotational subspaces spanned by pairs of amplitudes t_n and phase angles τ_n ($n = 1, 2, ..., N − 2$). After the N-ring is positioned into *standard orientation*, the Cartesian coordinates of the ring atoms are linked to the deformation coordinate parameters R and (t_n, τ_n) with the following formulas:[54]

$$x_j = -R \cos\left[\frac{2\pi(j-1)}{N}\right] + \sum_{n=1}^{N-2} t_n \cos\left[\tau_n - \frac{2\pi(n+1)(j-1)}{N}\right] \tag{3}$$

$$y_j = R \sin\left[\frac{2\pi(j-1)}{N}\right] + \sum_{n=1}^{N-2} t_n \sin\left[\tau_n - \frac{2\pi(n+1)(j-1)}{N}\right] \tag{4}$$

where all z_j components as the out-of-plane deviations are related to puckering coordinates in eqs 1 and 2.

With the Cremer−Pople ring puckering coordinates and the recently developed ring deformation coordinates, one obtains a comprehensive, quantitative, and intuitive description of ring conformations of any N-membered ring.[47,54] Furthermore, the potential-energy surface (PES) or free-energy surface (FES) in $3N − 6$ dimensions of the N-ring system can be reduced to two- or three-dimensional contour plots with deeper physical insight and higher interpretability.[53−67]

The success of these two curvilinear coordinate systems in describing ring conformations can be attributed to their generally applicable mathematical form for all N-rings; more

importantly, they turn out to be the natural choice in characterizing ring conformations and their changes because both the Cremer–Pople puckering coordinates and the ring deformation coordinates were inspired and derived from the normal vibrational modes.[51,54] Either the out-of-plane puckering or in-plane deformation/rearrangement of the N-ring is initialized by a molecular vibration or the mixing of several degenerate vibrations[68–70] acting as the leading parameter.[71–73] By adopting this conceptual approach, we aimed in this work at developing new curvilinear coordinates for more distinctive geometries besides ring structures. The novel curvilinear coordinates derived from molecular vibrations are expected to be especially useful in describing conformational changes and structural rearrangements involving multiple atoms simultaneously.

One may question the extension of the underlying rationale in ring coordinates (i.e., a specific vibration in a ring initiates puckering or deformation motion) to other molecular geometries in general. However, it has been widely recognized that molecular vibrations can drive chemical reactions by exciting a specific vibrational mode of the reactant along the reaction coordinate and in this way overcoming the energy barrier toward the product.[74,75] Crim, Zare, and others have demonstrated the possibilities of experimentally controlling the course of chemical reactions in gas phase and on metal surfaces by selectively exciting certain vibrational modes with a laser.[76–91] Therefore, the conceptual extension of ring coordinates to other geometries based on molecular vibrations has its physical foundation.
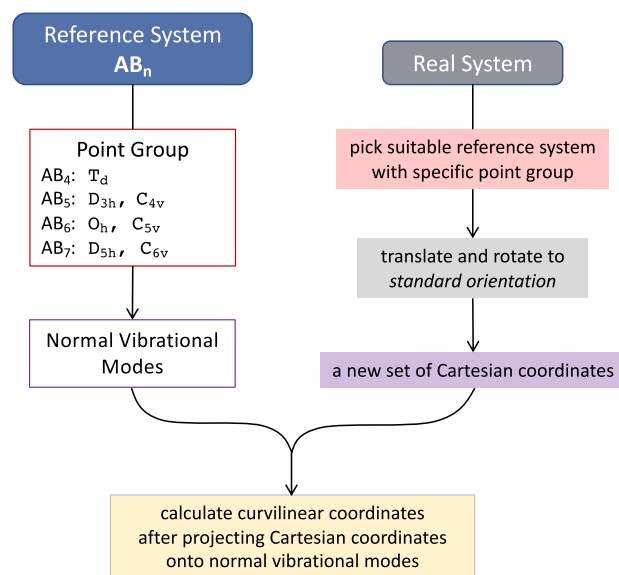

2.2. Vibration-Based Curvilinear Coordinates for *N*-Coordinate Geometry. Unlike for ring puckering/deformation coordinates, there is no direct analytic mathematical solution to connect each atom's Cartesian coordinates to the curvilinear coordinates describing N-coordinate systems due to the following reasons.

- The z-space can be separated from the x,y-space when defining the puckering[47] and deformation[54] coordinates for rings, respectively. However, the conformational changes in N-coordinate geometries involve atomic movement in the three-dimensional (3D) space which is more complex.

- The mathematical expression of either Cremer–Pople puckering or ring deformation coordinates has already encompassed the normal vibrational modes of the corresponding reference model systems (i.e., planar ring and regular polygon) implicitly. However, in the case of an N-coordinate geometry, we need to explicitly define the normal vibrational modes as the basis vectors spanning the configurational space of an N-coordinate geometry beforehand.

In the following, we elaborate how the curvilinear coordinates derived from normal vibrational modes for N-coordinate geometries are defined. Depending on the value of N, the geometry can be tricoordinate, tetracoordinate, pentacoordinate, hexacoordinate, heptacoordinate (e.g., IF$_7$), or octacoordinate (e.g., XeF$_8^{2-}$).[92] Within the same type of N-coordinate geometry, the relative spatial arrangement of the ligating atoms bonded to the central atom may vary. This complication can be resolved by utilizing point group information for the differentiation. For example, both $Fe(CO)_5$ and ClF_5 have a pentacoordinate geometry; however, the former is trigonal bipyramidal and the latter is square pyramidal, or expressed in

the point group language, the former has D_{3h} and the latter has C_{4v} symmetry.

As shown in Figure 1, we define in this work the curvilinear coordinates with respect to a tetracoordinate geometry with T_d

Figure 1. Schematic diagram illustrating the definition of curvilinear coordinates derived from normal vibrational modes for N-coordinate geometries.

symmetry, pentacoordinate geometries with D_{3h} and C_{4v} symmetry, hexacoordinate geometries with O_h and C_{5v} symmetry along with heptacoordinate geometries with D_{5h} and C_{6v} symmetry to cover the vast majority of coordination compounds with fluxionality.

The pentacoordinate geometry in C_{4v} symmetry is taken as an example in the following to stepwise illustrate how the curvilinear coordinate system derived from normal modes for an N-coordinate geometry is defined. The same procedure equally applies to other geometries with various point groups mentioned above.

2.2.1. Reference System for a Given Symmetry. As in the case of defining ring puckering coordinates with regard to the mean plane,[68–70] we first need to stipulate a reference system AB_n for the given symmetry, e.g., C_{4v}, where A is the central atom and n atoms of B are bonded to A as the first coordination sphere.

The definition of the reference system in Cartesian coordinates has to fulfill the following requirements:

- The central atom A denoted as the first atom is placed at the origin of the 3D Cartesian coordinate system.
- All A–B distances are set to be the same and assigned a value of r_1. This is equivalent to the situation that all atoms B are positioned on the surface of a sphere with radius r_1 and the center of sphere is placed at atom A.
- The relative positions of atoms B are adjusted under a symmetry constraint to guarantee that the geometrical center of AB_n is located at the position of atom A.

In addition, the following two conditions are optional.

- The z-axis is chosen to be the highest n-fold rotation axis of AB_n.
- Atoms B are grouped according to their z-values from top to bottom. If the first group of B has more than one atom,

the first atom within this group is placed right above the +x-axis ($y = 0$) and the remaining atoms are numbered counterclockwise when looking into the direction from atom 2 to atom 1. If the first group of B has only one atom, then this atom is positioned on the z-axis. Meanwhile, the first atom of the second group is positioned in the +x direction ($y = 0$).

For example, the reference system AB_5 with the C_{4v} point group (shown in Figure 2) has 18 Cartesian coordinates
Figure 2. Ball-and-stick representation for the reference system AB_5 with C_{4v} symmetry in Cartesian coordinates. The schematic Cartesian axes are shown for illustrating directions while the true origin is at the first atom A.

collected in matrix $\mathbf{R_0}$ with dimension 6×3 shown in eq 5. The three columns correspond to x, y, and z components and the six rows correspond to the six atoms of the reference system ordered according to the above description. The first row specifies the position of A at the origin point.

$$\mathbf{R_0} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & r_1 \\ Gr_1 & 0 & -Cr_1 \\ 0 & Gr_1 & -Cr_1 \\ -Gr_1 & 0 & -Cr_1 \\ 0 & -Gr_1 & -Cr_1 \end{bmatrix} \tag{5}$$

where $G = \sqrt{15}/4$, $C = 1/4$, and r_1 is the radius depending on the real system, which will be clarified below.

A reference system for a given symmetry operates like a template with fixed shape, which can be scaled by r_1. Furthermore, it serves as the basis for deriving the normal vibrational modes, which are independent of r_1.

2.2.2. Normal Vibrational Modes of Reference System. In order to span the complete configuration space of the reference system AB_n with a given symmetry, we need to derive one set of normal vibrational mode vectors acting as the basis. We employ for this purpose the following two-step procedure.

First, a model Hamiltonian accounting only for the pairwise nuclear charge repulsion is used to describe the interatomic forces within the reference system geometry (with r_1 temporarily taking an arbitrary value between 1 and 2 Å) leading to a model Hessian matrix which is calculated analytically. With the assumption that all atoms in AB_n have identical unit atomic masses (1 amu), the normal-mode analysis is carried out leading to an initial set of $3M - 6$ normal vibrational modes where $M = n$

+ 1. Besides, three rotational normal modes calculated with massless Eckart conditions[93,94] are obtained as column vectors $\mathbf{r_1}$, $\mathbf{r_2}$, and $\mathbf{r_3}$. (Please note that $\mathbf{r_1}$, $\mathbf{r_2}$, and $\mathbf{r_3}$ must not be confused with r_1, r_2, and r_3 representing amplitudes.)

Second, this initial set of $3M - 6$ normal modes is fine-tuned within the internal vibrational space by pairwise rotation according to the following rules:

(1) Two nondegenerate normal vibrations with the same irreducible representation can be mixed via a 2×2 rotation matrix leading to another two normal vibrations with the same symmetry.

(2) The first vibrational mode should always be the totally symmetric breathing mode of the present point group. The amplitude for all n atoms B in this vibrational mode vector must be identical, while the central atom A has no contribution.

(3) The atom A can be distorted only in the last three normal modes, which correspond to the relative translation between atom A and the remaining n atoms B in x, y, and z directions.

(4) Doubly degenerate modes (denoted as E and $E^{\dagger}$) or triply degenerate modes (T, $T^{\dagger}$, and $T^{\ddagger}$), can be pairwise rotated among themselves to fulfill the following requirements that

   (a) for the E or T mode, the distortions in the z direction and/or y direction are zero if possible,

   (b) for the $T^{\dagger}$ mode, the distortions in the y direction and/or x direction are zero if possible, and

   (c) the $E^{\dagger}$ or $T^{\ddagger}$ mode can be obtained by orthonormal condition.

Pairwise rotation as described between any two normal vibrational modes is a unitary transformation that keeps the orthonormality of $3M - 6$ normal modes and greatly simplifies the basis vibration vectors for later use.

Figure 3 shows all 12 normal vibrational modes of the AB_5 reference system in the C_{4v} point group. The normal mode vectors $\{\mathbf{l_i}\}$ ($i = 1, 2, ..., 3M - 6$) shown as $(M \times 3)$-dimensional matrices are orthonormal to each other. The collection of normal vibrational modes we derived for the other reference systems can be found in Appendices A.2−A.5.

2.2.3. Real System in Standard Orientation. For a real molecular compound with N-coordinate geometry as its core, the central N-coordinate part ("real system") deviates more or less from the reference geometry with a given symmetry during conformational changes or reaction processes. It would be ideal to express such distortions in terms of the normal vibrational modes that we derived for selected reference systems. In order to do so, we have to order the atomic labels of the real system according to those of the reference system for consistency and then place the real system into a particular position, where its internal coordinate space matches exactly the internal vibrational space of the reference system without any contamination from the translational or rotational space of the reference system.[95,96] This requires the following *standard orientation* to be imposed on the real system geometry:

• The initial Cartesian coordinates of the real system with N-coordinate geometry are recorded as $\mathbf{X}$, which is an $M \times 3$ matrix.

• The real system needs to be translated so that its geometrical center is positioned at the origin of Cartesian coordinate system, current Cartesian coordinates of the real system are collected in $\mathbf{X_c}$.
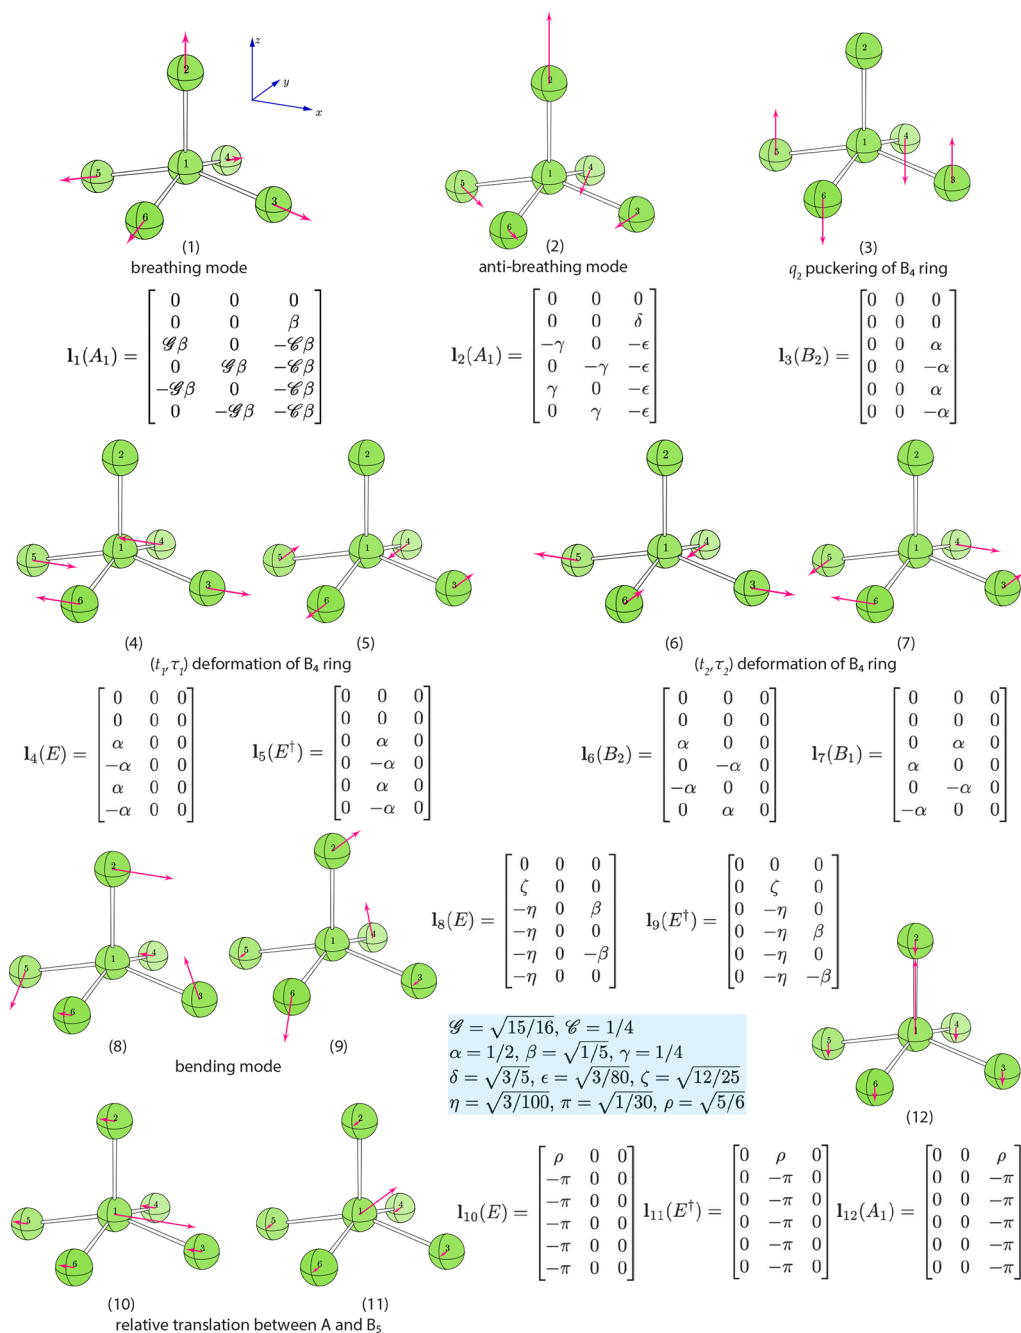

Figure 3. Twelve normal vibrational modes for the AB_5 reference system with C_{4v} symmetry. Below the ball-and-stick representations are the labels and brief descriptions of the normal modes. The irreducible representation and the mode vector for each vibration are also shown.

- The real system is then rotated in the 3D space so that its Cartesian coordinates denoted $\mathbf{X}_r$ are orthogonal to the rotational modes $\{\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3\}$ of the reference system. This final set of Cartesian coordinates $\mathbf{X}_r$ is named *standard orientation* for the real system.

The rotation of the real system by a rotation matrix $\mathbf{u}$ can be expressed by the product of three 3×3 elemental rotation matrices

$$\mathbf{u} = \mathbf{u}_z \mathbf{u}_y \mathbf{u}_x \qquad (6)$$

where $\mathbf{u}_x$, $\mathbf{u}_y$, and $\mathbf{u}_z$ define the rotation around x-, y-, and z-axes, respectively.

$$\mathbf{u}_x = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\theta_x & -\sin\theta_x \\ 0 & \sin\theta_x & \cos\theta_x \end{bmatrix} \quad \mathbf{u}_y = \begin{bmatrix} \cos\theta_y & 0 & \sin\theta_y \\ 0 & 1 & 0 \\ -\sin\theta_y & 0 & \cos\theta_y \end{bmatrix}$$

$$\mathbf{u}_z = \begin{bmatrix} \cos\theta_z & -\sin\theta_z & 0 \\ \sin\theta_z & \cos\theta_z & 0 \\ 0 & 0 & 1 \end{bmatrix} \qquad (7)$$

This leads to

$$\mathbf{X}_r = \mathbf{X}_c \mathbf{u} \qquad (8)$$

Figure 4. $\{r_5, \phi_5\}$ pseudorotational cycle specifying the (t_2, τ_2) deformation of the B_4 ring within the reference system AB_5 in C_{4v} symmetry (see Table 1). In the center of the cycle is the reference geometry for AB_5 with $r_1 = 1.5$ Å, and surrounding the cycle are the representative geometries for $r_5 = 0.35$ Å and different ϕ_5 values starting from 0° with the interval of 22.5° while all other r_m values (except r_1) are 0. The representative geometries are shown in the perspective of looking downward from atom 2 (red) to atom 1 (green), highlighting the in-plane deformation of the B_4 ring consisting of atoms 3–6.

We rearrange the Cartesian coordinates $\mathbf{X}_c$ and $\mathbf{X}_r$ from matrix form into the $(1 \times 3M)$-dimensional row vector form as $\vec{\mathbf{X}}_c$ and $\vec{\mathbf{X}}_r$; then a $(3M \times 3M)$-dimensional block diagonal matrix $\mathbf{U}$ is constructed with rotation matrix $\mathbf{u}$ as diagonal blocks and $\mathbf{0}_{3\times3}$ for nondiagonal blocks.

By definition, the standard orientation requires that

$$\begin{cases} \vec{\mathbf{X}}_r \mathbf{r}_1 = \vec{\mathbf{X}}_c \mathbf{U} \mathbf{r}_1 = 0 \\ \vec{\mathbf{X}}_r \mathbf{r}_2 = \vec{\mathbf{X}}_c \mathbf{U} \mathbf{r}_2 = 0 \\ \vec{\mathbf{X}}_r \mathbf{r}_3 = \vec{\mathbf{X}}_c \mathbf{U} \mathbf{r}_3 = 0 \end{cases} \tag{9}$$

where $\vec{\mathbf{X}}_c$, $\mathbf{r}_1$, $\mathbf{r}_2$, and $\mathbf{r}_3$ are already known so that only three rotation angles θ_x, θ_y, and θ_z remain as the unknowns contained in $\mathbf{U}$, which can be determined by iteratively solving this system of nonlinear equations.

However, practically solving the above system of equations with numerical methods could lead to an undesired solution as multiple sets of solutions could exist. This issue arises when the starting geometry in Cartesian coordinates $\mathbf{X}_c$ is close to another undesired standard orientation. As a remedy, the arbitrariness of rotation matrix $\mathbf{u}$ may be eliminated by minimizing the root mean-square deviation (RMSD) between the Cartesian coordinates $\mathbf{X}_c$ and the reference system, which has been proven by Kudin and Dymarsky[97] to be closely related to the well-known Eckart axis conditions. In this work, we adopt the quaternion-based algorithm of Kearsley[98] to first rotate the real system. Noteworthy is that before calculating the best-fit

alignment between real system and reference system, the A–B distance r_1 in the reference system is temporarily set to be the averaged A–B distance of the real system. With the real system rotated, its Cartesian coordinates change from $\mathbf{X}_c$ to $\mathbf{X}_f$ and the standard orientation can be unambiguously obtained by solving the system of equations in eq 10

$$\begin{cases} \vec{\mathbf{X}}_r \mathbf{r}_1 = \vec{\mathbf{X}}_f \mathbf{U} \mathbf{r}_1 = 0 \\ \vec{\mathbf{X}}_r \mathbf{r}_2 = \vec{\mathbf{X}}_f \mathbf{U} \mathbf{r}_2 = 0 \\ \vec{\mathbf{X}}_r \mathbf{r}_3 = \vec{\mathbf{X}}_f \mathbf{U} \mathbf{r}_3 = 0 \end{cases} \tag{10}$$

where $\vec{\mathbf{X}}_r$ is guaranteed to be the desired standard orientation calculated by numerical equation solver because $\mathbf{X}_f$ is close to $\mathbf{X}_r$ and $\theta_x = \theta_y = \theta_z = 0$ can be used as the initial guess. Usually, the calculation of eq 10 converges after one iteration.

2.2.4. Calculation of Curvilinear Coordinates. Once the real system is positioned in the appropriate standard orientation, its geometry $\mathbf{X}_r$ can be completely described by the set of $3M - 6$ normal vibrational modes of the corresponding reference system AB_n.

The determination of the real system geometry along the directions of normal vibrations is calculated by the projection of Cartesian coordinates $\mathbf{X}_r$ onto each normal mode vector $\mathbf{l}_i$ ($i = 1, 2, ..., 3M - 6$) using the dot product d_i

$$d_i = \vec{\mathbf{X}}_r \vec{\mathbf{l}}_i^T \tag{11}$$

where $\vec{\mathbf{X}}_r$ and $\vec{\mathbf{l}}_i$ take the row vector form of matrices $\mathbf{X}_r$ and $\mathbf{l}_i$, respectively, and superscript T indicates the transpose.

Up to this point, we are able to describe the geometry of the real system merely by the set of $3M - 6$ projection values $\{d_i\}$ as long as corresponding normal vibrational modes for the reference system have been determined beforehand. Besides, for those doubly or triply degenerate vibrations we derived for the reference systems, it would be more useful if these degenerate vibrations are combined using pseudorotational cycles in polar coordinates or using the conformational globe in cylindrical/spherical coordinates as for ring puckering coordinates. Even for nondegenerate vibrational modes, they can also be grouped together for convenience.

Along these lines, we define three types of curvilinear coordinate sets for an N-coordinate geometry:

(i) nondegenerate curvilinear coordinate $\{r_m\}$

$$r_m = \mathcal{F}d_m \tag{12}$$

where $\mathcal{F}$ is the largest atomic amplitude within the normal mode vector $\mathbf{l}_m$ associated with the projection value d_m. For example, within the first breathing mode of the reference system AB_5 in C_{4v} symmetry, all four atoms B have the largest amplitude as $\sqrt{\alpha^2 + \beta^2} = 1/2$. Therefore, $\mathcal{F}$ takes the value of $1/2$ for this particular vibrational mode.

With $\mathcal{F}$ as a scaling factor, r_m has the same fundamental unit of distance as d_m, generally expressed in Angstrom units. r_m can be either positive or negative.

(ii) doubly degenerate curvilinear coordinates $\{r_m, \phi_m\}$

$$\begin{cases} r_m \cos \phi_m = \mathcal{F}d_m \\ r_m \sin \phi_m = \mathcal{F}d'_m \end{cases} \tag{13}$$

where d_m and d'_m are the projections from real system geometry $\mathbf{X}_r$ onto a pair of doubly degenerate (E and $E^\dagger$) vibrational modes and the curvilinear coordinates $\{r_m, \phi_m\}$ are calculated by solving above system of equations.

This curvilinear coordinate parameter set specifies a polar coordinate system where we expect that

$$r_m \geqslant 0, \; 0° \leqslant \phi_m < 360° \tag{14}$$

During a relaxed PES scan or reaction pathway, r_m is allowed to take a negative value with the following equivalence relation.

$$\{r_m, \phi_m\} \equiv \{-r_m, \phi_m \pm 180°\} \tag{15}$$

For a fixed amplitude r_m, a pseudorotational cycle arises when the phase angle ϕ_m gradually changes, as shown in Figure 4. When ϕ_m equals $0°/180°$, the second degenerate vibration has no contribution, and when ϕ_m equals $90°/270°$, the contribution from the first degenerate vibration vanishes. Otherwise, both vibrations contribute to determine the geometry of the real system.

iii. triply degenerate curvilinear coordinates $\{r_m, \theta_m, \phi_m\}$

$$\begin{cases} r_m \cos \theta_m = \mathcal{F}d_m \\ r_m \sin \theta_m \sin \phi_m = \mathcal{F}d'_m \\ r_m \sin \theta_m \cos \phi_m = \mathcal{F}d''_m \end{cases} \tag{16}$$

where d_m, d'_m, and d''_m are the projections from $\mathbf{X}_r$ onto a triad of triply degenerate (T, $T^\dagger$, and $T^\ddagger$) vibrational modes and $\{r_m, \theta_m, \phi_m\}$ determines a spherical coordinate system where we expect that

$$r_m \geqslant 0, \; 0° \leqslant \theta_m \leqslant 180°, \; 0° \leqslant \phi_m < 360° \tag{17}$$

Also, r_m can take a negative value with the following equivalence relation.

$$\{r_m, \theta_m, \phi_m\} \equiv \{-r_m, 180° - \theta_m, \phi_m \pm 180°\}$$
$$\equiv \{r_m, -\theta_m, \phi_m \pm 180°\} \tag{18}$$

This set of curvilinear coordinate parameters controls the contribution from three vibrations to the real system geometry in a similar fashion as the doubly degenerate set. For a given value of r_m, we adopt the idea of conformational globe from ring puckering coordinates for describing the conformational variation in N-coordinate geometries as shown in Figure 6.

Consequently, the geometry of the real system in the standard orientation with regard to the selected reference system AB_n having M atoms can be accurately determined by $3M - 6$ curvilinear coordinate parameters of the above three types.

Table 1 summarizes seven sets of curvilinear coordinate parameters we constructed for the AB_5 system with C_{4v}

Table 1. Summary of 12 Curvilinear Coordinate Parameters in 7 Sets Based on 12 Normal Vibrational Modes for the Reference System AB$_5$ in C$_{4v}$ Symmetry

| normal mode	curvilinear coordinates	symmetry	description
1	r_1	A_1	AB_5 breathing

symmetry. The geometry of the reference system is determined once r_1 has been calculated with eq 12.

Note that we have combined the sixth and seventh normal modes into a pair of doubly degenerate curvilinear coordinates $\{r_5, \phi_5\}$ although these two modes have different symmetries. This is because these two vibrational modes are the basis vectors for the (t_2, τ_2) deformation of the B_4 ring[54] and they are similar in their mathematical form with identical $\mathcal{F}$ values.

Figure 4 shows a $\{r_5, \phi_5\}$ pseudorotational cycle where a single curvilinear coordinate parameter ϕ_5 determines the geometrical variation in AB_5. Figure 5 illustrates a two-dimensional (2D) PES by relaxed scanning r_5 and ϕ_5 simultaneously for the PF_5 molecule as a showcase example to demonstrate one possibility of applying the curvilinear coordinates developed in this work to model polytopal rearrangements. Besides, we have combined the pair of degenerate vibrations (10th and 11th) with the 12th vibrational mode into a triply degenerate set of curvilinear coordinates $\{r_7, \theta_7, \phi_7\}$ because these three vibrational modes are similar in their mathematical form and all of them describe the relative translations of the central atom.

2.2.5. Conversion from Curvilinear Coordinates into Cartesian Coordinates. During a quantum chemical modeling of an N-coordinate compound with its geometry described with the curvilinear coordinates, the back-conversion from curvilinear coordinates to Cartesian coordinates is needed.
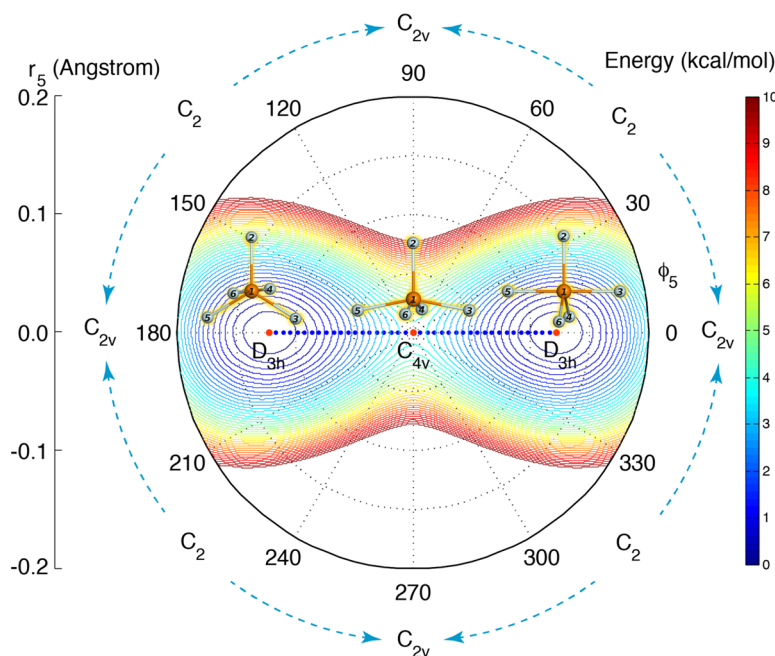

Figure 5. 2D PES of PF_5 obtained by relaxed scan of $\{r_5, \phi_5\}$ based on the AB_5 reference system in C_{4v} symmetry. An energy scale is given on the right side and data points with energy values over 10 kcal/mol have been removed from the contour plot. A minimum-energy path characterizing the Berry pseudorotation[9,10] is indicated by the blue dots, where two lowest energy structures in D_{3h} symmetry and the first-order saddle point structure in C_{4v} symmetry are marked with red dots. Geometries with $\phi_5 = 0°/90°/180°/270°$ have C_{2v} or higher symmetries, while the rest of the geometries have C_2 symmetry. Calculations were carried out at the B3LYP/cc-pVTZ level. A 3D representation of this PES is included in the Supporting Information.

For this purpose, we first calculate the projection values d_i from curvilinear coordinates according to eqs 12, 13, and 16. Then, the Cartesian coordinates $\mathbf{X}_r$ in standard orientation are calculated via

$$\mathbf{X}_r = \sum_{i=1}^{3M-6} d_i \mathbf{l}_i \qquad (19)$$

which utilizes the orthonormality of the normal modes.

*2.2.6. Wilson **B**-Matrix and Geometry Optimization.* Using the curvilinear coordinates defined above, to optimize equilibrium geometries and transition states with quasi-Newton algorithms[99,100] in quantum chemical packages requires the Wilson **B**-matrix and its derivative d**B**-matrix defined in eqs 20 and 21, respectively.

$$B_{n,i} = \frac{\partial q_n}{\partial x_i} \qquad (20)$$

$$dB_{n,i,j} = \frac{\partial^2 q_n}{\partial x_i \partial x_j} \qquad (21)$$

where q_n is an internal coordinate or curvilinear coordinate parameter while x_i and x_j are Cartesian coordinate components of $\mathbf{X}_r$ in standard orientation.

We did not derive yet an analytic Wilson **B**-matrix and its derivatives. Therefore, for the time being these matrices are calculated numerically according to the formula listed in Appendix A.1.

2.2.7. Extension to Larger Molecules with N-Coordinate Core. For those coordination compounds having more than one coordination sphere (e.g., $Fe(CO)_5$), the curvilinear coordinates developed in this work only determine the geometry of the N-coordinate core fragment. We employed the **Z**-matrix

formulation by combining the curvilinear coordinates describing the core fragment and the internal coordinates (e.g., bond length, bond angle, and dihedral angle) describing the outer spheres, so that our curvilinear coordinate system is seamlessly incorporated into the internal coordinate system implemented in most quantum chemical packages. In this way, conventional geometry optimization machinery can be employed with the newly developed curvilinear coordinates for larger coordination compounds.

3. COMPUTATIONAL DETAILS

In this work, we have developed a utility program CURVI that converts Cartesian coordinates into curvilinear coordinates and vice versa. Programs written to carry out geometry optimization in terms of curvilinear coordinates have been incorporated into the *ab initio* program COLOGNE19.[101]

All quantum chemical calculations including single-point energy, geometry optimization, relaxed PES scan, harmonic vibrational frequencies and intrinsic reaction coordinate (IRC) path were performed with the *ab initio* program packages COLOGNE19[101] and Gaussian 16.[102] Density functional theory (DFT) with an UltraFine integration grid was employed to model all systems in this work. The PF_5 molecule in Figure 5 was calculated at the B3LYP/cc-pVTZ level,[103−107] the $Fe(CO)_5$ and $Ga^{III}(mda)_3$ compounds were calculated using the Minnesota hybrid functional M06L[108] with Ahlrichs' Def2SVP basis set,[109,110] and all molecules without metal atoms were calculated at M06-2X/Def2SVP level.[111]

Relaxed PES scans were conducted by combining the curvilinear coordinates describing the core fragment with internal coordinates describing the outer-layer atoms within the **Z**-matrix formulation. Each scan step was considered as optimized when the maximum force is below 0.0025 au and the maximum geometrical deviation is below 0.01 au. The geometry
Figure 6. Conformational globe spanned by the parameter set $\{r_7, \theta_7, \phi_7\}$ specifying the translation of central atom A within the AB_5 reference system ($r_1 = 1.5$ Å) in C_{4v} symmetry (see Table 1). Any point on the globe surface has $r_7 = 0.3$ Å while all other r_m values (except r_1) are 0. Some distinct longitudes and latitudes are shown, including the equator ($\theta = 90°$) in red and the Tropic of Cancer ($\theta = 66.5°$) and the Tropic of Capricorn ($\theta = 113.5°$) in magenta. Among five representative structures ($\phi_7 = 0°$, $\theta_7 = 0°/66.5°/90°/113.5°/180°$), bond 1−2 first shortens and then elongates (controlled by $\sin\theta_7$), bond 1−3 elongates and bond 1−5 shortens (controlled by $\cos\theta_7$) continuously from north pole to south pole. Among seven representative structures on the equator ($\theta_7 = 90°$, $\phi_7 = 180°/210°/240°/270°/300°/330°/360°$), bond 1−2 shortens (controlled by $\cos\phi_7$) from left to right, bond 1−6 first shortens and then elongates, and bond 1−4 changes in the opposite way (controlled by $\sin\phi_7$).

optimization for stationary points was carried out with a tight convergence criterion.

IRC calculations were performed in Cartesian coordinates without mass-weighting in order to map out the minimum-energy path (MEP). Most MEPs in this work were obtained using Hessian-based predictor-corrector (HPC) integrator[112−114] with a stepsize of 0.05 bohr and analytic Hessian every five steps. For larger compounds discussed in sections 4.2 and 4.3, either the GS2[115,116] or local quadratic approximation (LQA)[117,118] algorithm was employed as the path integrator, with the stepsize of 0.20−0.50 bohr.

4. RESULTS AND DISCUSSION

The Berry pseudorotation of PF_5 molecule[9,10] has been shown in Figure 5 as an example where the multidimensional PES is reduced to a 2D PES spanned by the curvilinear coordinate pair $\{r_5, \phi_5\}$ and the reaction path connecting the stationary points is then straightforwardly determined. We need to note that the choice of the reference system AB_5 in C_{4v} symmetry for this

example is based on its known mechanism; i.e., the transition state takes a square pyramidal (C_{4v}) geometry. However, when investigating fluxional molecules with uncertain mechanisms, we have to start from the local minimum structures (reactants/products) on the PES. Besides, the scanned PES with two degrees of freedom can be further simplified into a 1D PES if the reaction coordinate is properly chosen.

that the nonrigidity of SF$_4$ arises from Berry pseudorotation,[9,10] where the axial F−S−F angle closes accompanied by the opening of the equatorial F−S−F angle, passing through a TS with C_{4v} symmetry.

We used the curvilinear coordinates derived from the AB$_4$ reference system in T_d symmetry (see Appendix A.2) to describe the Berry mechanism of SF$_4$ pseudorotation. Ideally, a tetracoordinate reference system in C_{2v} symmetry would best fit the symmetry of SF$_4$. However, by definition, the reference

different temperatures, SF$_4$ is considered fluxional as it undergoes fast exchange of ligand positions at room temperature.[120−122] Klemperer and co-workers concluded in 1975[123]

system is required to position the central atom A at the geometrical center. Under this constraint, for SF$_4$ the AB$_4$ reference system with T_d symmetry is the only solution.

The two axial fluorine atoms were labeled as the first two ligands (atoms 2 and 3), and the optimized geometry of SF$_4$ was

then expressed in curvilinear coordinates collected in Table 2. The amplitude r_1 defines the overall size of SF$_4$ structure while the remaining r_m values specify to what extent the geometry deviates from the reference system with T_d symmetry. The parameter set $\{r_2, \phi_2\}$ has a positive amplitude and a phase angle $\phi_2 = 270°$. This implies that SF$_4$ geometry has a dominating contribution from the third normal vibrational mode in reverse direction ($\sin \phi_2 = -1$) and no contribution from the second normal mode ($\cos \phi_2 = 0$) relative to the reference geometry in T_d symmetry (see Table 10 in Appendix A.2). Similarly, the

SF$_4$ geometry ($\sin \theta_4 \cos \phi_4 = 1$) while the seventh ($\cos \theta_4 = 0$) and eighth ($\sin \theta_4 \sin \phi_4 = 0$) do not.

In order to model the Berry pseudorotation process, we employed the coordinate driving approach[124−129] by carrying out a relaxed PES scan of selected curvilinear coordinate(s) locating the TS in the first place. By inspection of all nine normal vibrations for the AB$_4$ reference system shown in Figure 44 (Appendix A.2), we found the third normal mode is closely related to the Berry process if the F atoms in SF$_4$ move along this mode in the opposite direction to lower the axial fluorine atoms

direction, we performed a relaxed PES scan by stepwise increasing the amplitude r_2.

As shown in Figure 7, the energy increases smoothly with an increasing r_2 value until it encounters a maximum point around $r_2 = 0.88$ Å, followed by a few points with lower energies. We did

not continue the relaxed PES scan all the way down to reach another minimum point close to the product structure, instead the scan was terminated immediately, when an obvious maximum point was found. This strategy was based on two reasons:

- The maximum point obtained from the relaxed scan is an approximate transition state (aTS) that is already close to the true transition state (TS). The TS point connects the
Figure 40. 2D PES of SF_4 obtained by a relaxed scan of θ_4 and ϕ_4 based on the AB_4 reference system in T_d symmetry. The MEP characterizing the lever pseudorotation mechanism is traced by the white dots connected with a dashed line. The green, red, and cyan round dots represent reactant, aTS, and product, respectively. All other cyan dots represent SF_4 in equilibrium geometry, red dots represent first-order saddle points of the lever mechanism, and the black dot represents a second-order saddle point. The color bar on the right side shows the energy scale in kcal/mol. A 3D representation of this PES is included in the Supporting Information.
Figure 41. Energy profile along the MEP of a lever mechanism for SF_4. The green, red, and cyan round dots represent reactant, TS, and product respectively. The mirror plane of the C_s symmetric TS contains F3 and F4 atoms and halves the F2−S1−F5 angle.

entrance and exit channels, and the whole reaction path can be easily mapped out starting from this point by following the vibrational eigenvector with negative PES curvature. Therefore, it is unnecessary to continue the relaxed scan past the aTS point until a minimum point is found.

We reoptimized the geometry of the SF_4 molecule at the aTS point in order to locate the first-order saddle point (TS) on the PES. Then, the minimum-energy path (MEP) was traced going downhill from the TS in two directions, toward reactant and product, respectively.

Figure 8 shows the energy profile as a function of the reaction coordinate s, which is symmetric with regard to $s = 0$. The
Figure 42. Variation of the amplitude r_m along the MEP of the lever mechanism of SF_4.

calculated barrier height (without thermal correction) is 10.4 kcal/mol, being qualitatively consistent with experimentally measured activation free energy of 12.2 kcal/mol.[130]

We also monitored the variation of the curvilinear coordinates along the MEP of the Berry pseudorotation. Interestingly, we found that all phase angles θ_m/ϕ_m do not change along the whole reaction process, as indicated in Table 2 for the reactant geometry. Figure 9 shows how each amplitude value r_m changes with the reaction progress.

The amplitude r_2 chosen as the driving coordinate in the relaxed PES scan shows the most significant change along the path, it increases by 0.7 Å, while r_1 and r_3 both decrease by 0.5 Å. The amplitude r_4, associated with relative translation between the central S atom and four ligating F atoms does not change. In addition, this result indicates that the amplitude r_3 could be another parameter to be scanned when locating the aTS point (by decreasing it) as the parameter set $\{r_3, \theta_3, \phi_3\}$ at the reactant geometry specifies the fourth normal vibration, which corresponds to the lengthening of axial F··· F distance and shortening of equatorial F··· F distance (see Figure 44 in Appendix A.2).

An alternative fluxional process to the Berry pseudorotation of SF_4 molecule is the *lever mechanism*, which will be discussed below in section 4.5.2.

4.2. Berry Pseudorotation and Muetterties' Mechanisms of Pentacoordinate Trigonal-Bipyramidal Compounds.

The stereomutation of pentacoordinate compounds has fascinated chemists since the 1950s, when the fluxionality of PF_5 in solution was first discovered.[131] In 1960, Berry proposed a pseudorotation mechanism for the PF_5 molecule with trigonal bipyramidal (D_{3h}) geometry, where two axial F atoms and two equatorial F atoms are interconverted via a square pyramidal (C_{4v}) transition state (see Figure 5).[9,10] After an increasing number of trigonal bipyramidal compounds exhibiting fluxionality had been synthesized, Muetterties derived five permutation mechanisms interchanging the position of the ligands in the trigonal bipyramidal geometry.[6,132] However, two out of these five mechanisms are unlikely to happen due to high energy barriers. The remaining three mechanisms **M1–M3** are shown in Figure 10. Complementary to the Berry pseudorotation, Ugi and co-workers proposed a turnstile rotation mechanism to account for the stereomutation in a caged oxyphosphorane compound, where three out of five groups are rotated by 60° with regard to the other two.[133]

In 2010, Couzijn and co-workers revisited the polytopal rearrangements in a series of trigonal bipyramidal compounds with quantum chemical calculations and came to several assertions, which refreshed our view on the mechanistic detail in terms of atomic motions in pentavalent compounds.[18,134] The authors proved that Ugi's turnstile rotation in the caged oxyphosphorane structure is simply a Berry pseudorotation with lower symmetry by examining its topology parameter (i.e., difference between axial biting angle and equatorial biting angle) along the reaction path. They re-evaluated the three possible mechanisms **M1–M3** suggested by Muetterties (see Figure 10) with topology parameter and found that mechanisms **M2** and **M3** can be decomposed into two and three consecutive Berry pseudorotations respectively, although only one transition state exists.

In this work, we revisited Muetterties' three mechanisms **M1–M3** each exemplified by a pentacoordinate compound (see Figure 11) with our new curvilinear coordinates.

4.2.1. Berry Pseudorotation M1. **1** has a D_{3h} geometry; therefore, the Fe and C atoms are labeled in accordance with the AB_5 reference system with D_{3h} symmetry, leading to the curvilinear coordinates of **1** in Table 3. The optimized geometry of core fragment (central Fe atom and its first coordination sphere, i.e., C atoms) of **1** is very close to that of the reference system, as the amplitudes r_2 through r_6 are literally zero. We found that the seventh normal vibrational mode of the reference system (see Appendix A.3) is directly related to a Berry pseudorotation process, if this mode moves in the opposite direction. Coincidently, the parameter set $\{r_5, \theta_5, \phi_5\}$ in **1** corresponds exactly to the seventh normal mode ($\cos \theta_5 = -1$) and a relaxed PES scan for increasing r_5 ensures driving the whole compound toward Berry pseudorotation process, as shown in Figure 12.

After locating the TS, we mapped out the MEP of the Berry pseudorotation for this system as shown in Figure 13. Examination of the curvilinear coordinates along the MEP revealed that all phase angles (θ_m/ϕ_m) do not change compared to the reactant geometry, which is in the same situation as found for the Berry pseudorotation of SF_4 discussed above. From the variation of the amplitude values shown in Figure 14, we found that amplitude r_5 has the largest increase followed by r_3. This result demonstrates that the seventh normal mode intrinsically corresponds to a Berry pseudorotation process, qualifying this
Figure 44. List of 9 normal vibrational modes for AB_4 reference system with T_d symmetry. Below the ball-and-stick representations are the labels and brief descriptions of the normal modes. The irreducible representation and the mode vector for each vibration are also shown.

mode as suitable parameter for a relaxed PES scan. The reason why r_3 has a significant change is because the third normal mode in the opposite direction ($\cos \phi_3 = -1$) corresponds to the opening of the equatorial C−Fe−C bite angle (see Figure 45 in Appendix A.3), which is also observed in the Berry pseudorotation. The changes in the amplitude values of r_2, r_4, and r_6 are only marginal.

4.2.2. Muetterties Mechanism M2. According to the work of Couzijn, Lammertsma, and co-workers,[18] the seemingly complicated 3-fold cyclic permutation mechanism **M2** consists of two consecutive Berry pseudorotation steps. Following this idea, we first identified in **2** the pivot atom, which does not participate the Berry pseudorotation involving the other four ligating atoms. As shown in Figure 15, we chose one equatorial carbon atom of a biphenyl-2,2′-diyl group as the pivot atom (no. 3) and the other atoms were labeled according to the reference system. Then the geometry of the core fragment in **2** is expressed in curvilinear coordinates shown in Table 4.

As revealed from the previous example, the seventh normal mode of the AB_5 reference system with D_{3h} symmetry is closely related to a Berry pseudorotation. The curvilinear coordinates

can ideally describe the Berry mechanism if the phase angle θ_5 is expected to be close to 180° while r_5 is positive. We found that in the reactant geometry of **2** (see Table 4) the amplitude r_5 is positive. $\cos \theta_5 = 0.75$ reveals the dominance of the seventh normal vibration over the eighth ($\sin \theta_5 \sin \phi_5 = 0.10$) and ninth ($\sin \theta_5 \cos \phi_5 = 0.65$) vibrations because 0.75 is closer to 1. However, the phase angle θ_5 specifies a reverse direction toward the desired Berry pseudorotation path. A simple solution to mitigate this issue is to push the amplitude r_5 into the negative direction. Therefore, we carried out a relaxed PES scan for **2** by decreasing the amplitude r_5 as shown in Figure 15 and the aTS point pertaining to mechanism **M2** was successfully located.

After the refinement of the TS point, the complete reaction path shown in Figure 16 was mapped out. Figures 17 and 18 show how the curvilinear coordinates (i.e., amplitudes and phase angles) change along the MEP.

Amplitude r_5 shows the largest variation with a steady decline along the whole path, r_3 starts to increase in the middle of the entrance channel while the increase of r_4 becomes obvious in the exit channel. We were particularly interested in the parameter set $\{r_5, \theta_5, \phi_5\}$ monitoring its contribution from the seventh normal

vibration compared with that from the eighth and ninth normal modes. Figure 18 shows that the phase angle θ_5 drops immediately toward 5° as the reaction starts. This ensures the dominance of the seventh normal mode as its cosine value of 0.996 is very close to 1. Although the phase angle θ_5 starts to increase in the middle of exit channel, its maximum value at the end is around 30° which still claims the dominant role of the seventh normal mode. Given the significant change in r_5 throughout the whole path, we conclude that the reaction path of the Muetterties mechanism **M2** of **2** is dictated by the continuous displacement of the seventh normal vibration of the corresponding reference system.

It seems that our findings are inconsistent with Couzijn's claim[18] that this mechanism consists of two consecutive Berry processes. However, one needs to be aware that their analysis was based on a so-called *topology parameter* that relies on the definition of an equatorial pivot atom in order to describe the Berry process. The well-suited topology parameter describing the entrance (exit) channel of **M2** mechanism is no longer suitable to describe the geometrical changes in the exit (entrance) channel. Couzijn and co-workers thus defined for this reaction two separate topology parameters whose values meet at the TS point.

Despite the simplicity introduced into the Muetterties mechanism **M2**, topology parameters are by nature discontinuous along the complete reaction path. In contrast, our curvilinear coordinate system provides a comprehensive and continuous description of the geometry along reaction path in terms of distortions from a reference geometry.

4.2.3. Muetterties Mechanism M3. Although Couzijn's work[18] suggests the location of an aTS point of the Muetterties mechanism **M3** for **3** via a relaxed PES scan following the Berry process led by the seventh normal vibrational mode as in the last example, the vibration library data (see Appendix A.3) suggest that the eighth normal mode is the most important motion describing this mechanism. One also has to consider that the seventh and eighth vibrations form a doubly degenerate pair. Therefore, we first reordered the atoms in the core fragment of **3** as shown in Figure 19 to ensure that the bending of O2−P1−O6 angle in the −y direction could optimally correspond to the

target mechanism. The geometry of the core fragment expressed in curvilinear coordinates is collected in Table 5.

Compared with the AB_5 reference geometry in D_{3h} symmetry, the relative contributions of the seventh, eighth, and ninth normal modes to the geometry of **3** are determined by the phase angles θ_5 and ϕ_5, as this set of pseudotriply degenerate normal modes is controlled by the parameter set $\{r_5, \theta_5, \phi_5\}$. Noteworthy is that the contribution from the seventh vibration ($\cos \theta_5 = 0.87$) to the reactant geometry is still dominating and the eighth vibration ($\sin \theta_5 \sin \phi_5 = -0.48$) is the second dominant vibration. Current phase angles for the eighth vibration correctly specify the desired motion responsible for the reaction mechanism **M3**. The relaxed PES scan was carried out by gradually increasing the amplitude r_5.

As shown in Figure 19, we located a maximum point at $r_5 = 1.02$ Å followed by a sudden decrease in energy leading to a cusp. However, the subsequent refinement showed that the geometry of this maximum point is already very close to the real TS point for mechanism **M3**, which means the approximate TS point was successfully identified through relaxed PES scan of r_5. On the basis of the refined TS point, a smooth MEP was mapped out as shown in Figure 20. The corresponding variation of the curvilinear coordinates along the MEP is shown in Figures 21 and 22.

The amplitude r_5 shows the most significant change before the TS by increasing from 0.1 to 1.2 Å. In the exit channel, changes of all amplitude values are only marginal, especially after $s = 5.0$ bohr. As amplitude r_5 is the major driving coordinate in Muetterties mechanism **M3** in the entrance channel, monitoring of the phase angles θ_5 and ϕ_5 is of great importance for the understanding of this mechanism. θ_5 gradually increases from 30° to 60° at the TS and ϕ_5 increases from 255° to 290°; i.e., the eighth normal mode ($\sin \theta_5 \sin \phi_5 = -0.48 \rightarrow -0.81$) takes over the role as the dominant vibration after $s = -12.5$ bohr compared to the seventh normal mode ($\cos \theta_5 = 0.87 \rightarrow 0.50$). The contribution from the ninth vibration remains low ($\sin \theta_5 \cos \phi_5 = -0.13 \rightarrow -0.30$).

Amplitude r_4 shows also a significant change in the entrance channel by increasing from 0.0 to 0.5 Å. The associated phase angle ϕ_4 increases from 68° to 130° at the TS point, indicating the prevailing contribution from the sixth normal mode over the
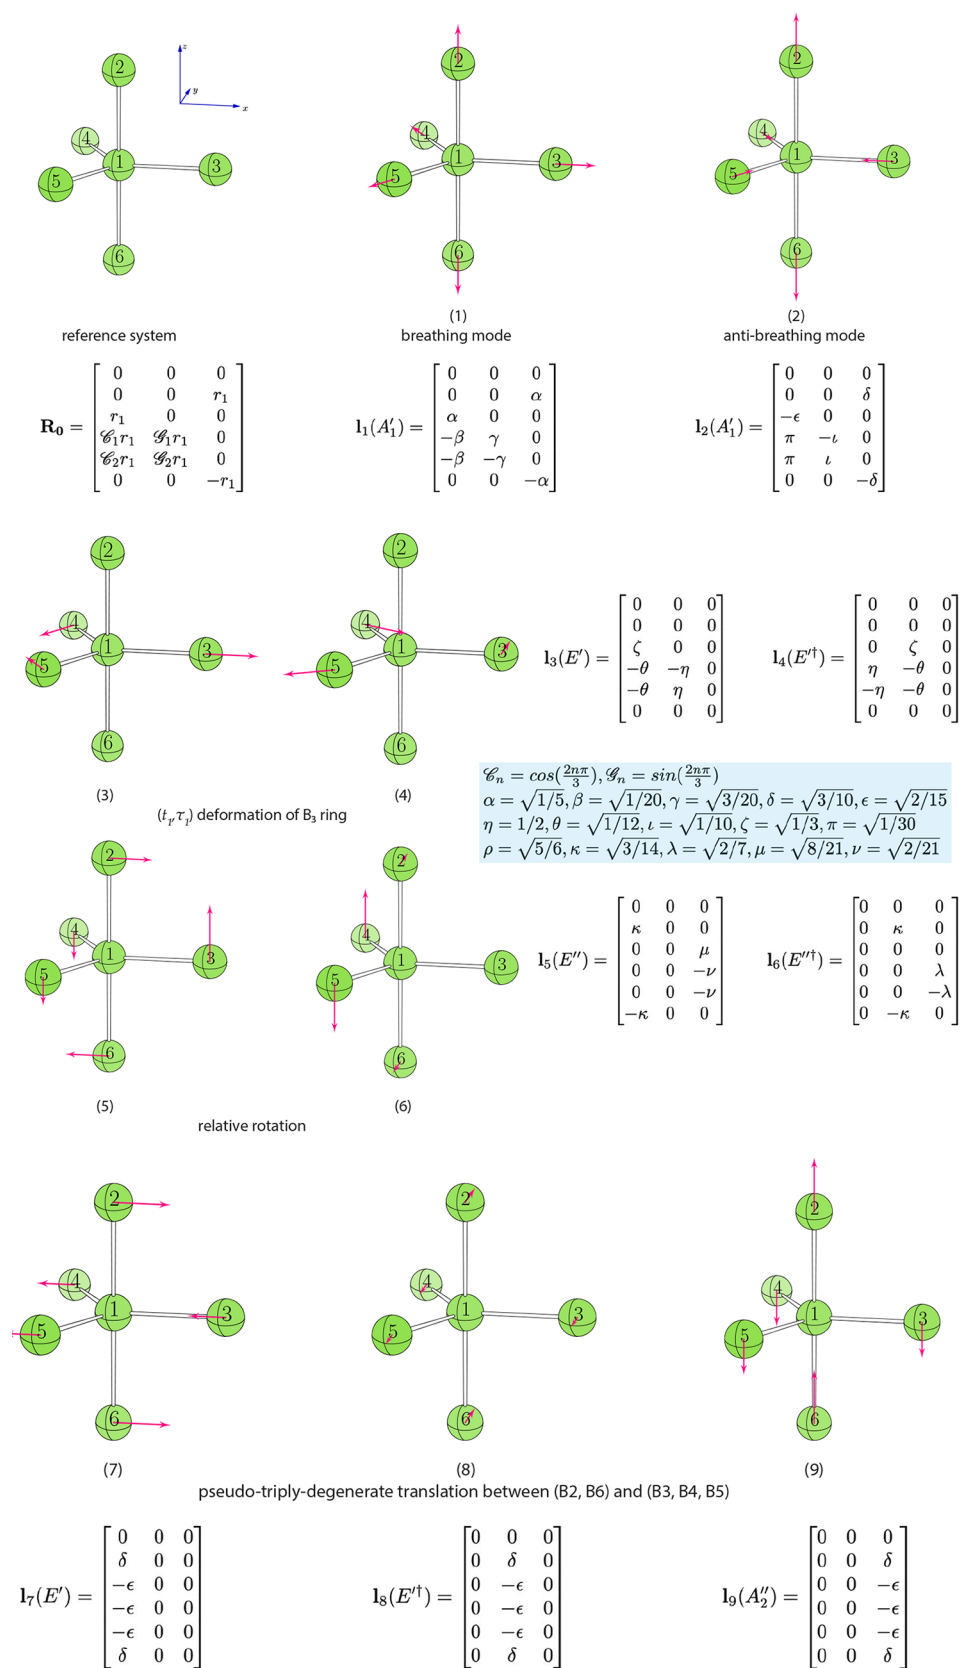

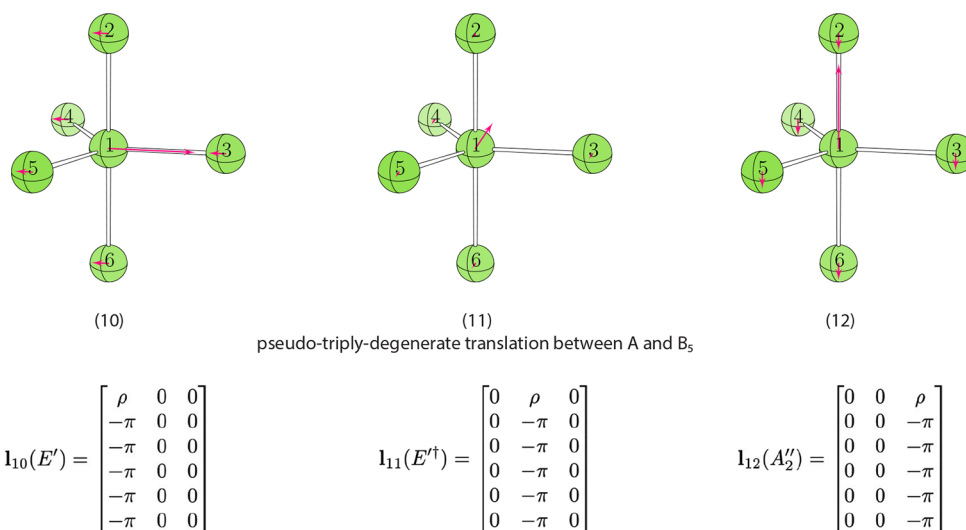

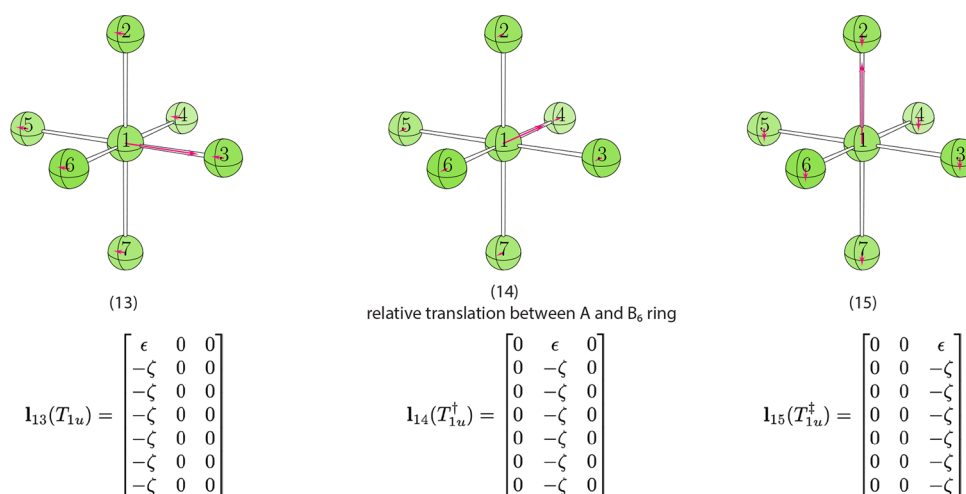

Figure 46. continued

Figure 46. List of 15 normal vibrational modes for AB_6 reference system with O_h symmetry. Below the ball-and-stick representations are the labels and brief descriptions of the normal modes. The irreducible representation and the mode vector for each vibration are also shown.

fifth. While the eighth normal mode brings the O2−P1−O6 angle into the −y direction, the sixth normal mode pulls the O6 atom into the −y direction but the O2 atom is pushed to +y direction. The combined effects of these two modes result in the O6 atom being lifted up in the −y direction while the motions for O2 atom are canceled out, leading to the square pyramidal TS.

The above analysis on mechanism **M3** is based on the present atomic ordering for the core fragment shown in Figure 19. We also could have chosen another more straightforward set of atomic ordering (i.e., pick the yellow C atom as the pivot) in order to utilize Couzijn's conclusion[18] that mechanism **M3** consists of three consecutive Berry processes expecting a dominating contribution from the seventh normal mode throughout the whole path. Important to note is that according to our findings, the initial assignment of reference to real system (i.e., ordering of atoms within the core fragment) is not strictly limited to only one possibility. This allows a certain flexibility, which makes our curvilinear coordinate system robust.

4.3. Bailar and Ray−Dutt Twists of Tris-chelate Metal Complexes. Tris-chelate metal complexes containing three chelating ligands typically adopt an octahedral (hexacoordinate) geometry in the center and they can undergo nondissociative ligand permutation processes (Figure 23), altering their helical chirality (i.e., from Δ to Λ form and vice versa).[29,138] Two well-known mechanisms for racemization of chiral tris-chelates are (1) the Bailar twist,[139] a trigonal twist around the real C_3 axis of a metal tris-chelate and (2) the Ray-Dutt twist,[140] a rhombic twist around a pseudo-C_3 axis. The different pathways describing these two conformational changes originate in the different rotation axes leading to D_{3h} and C_{2v} TSs for the Bailar and the Ray−Dutt twists, respectively. Twists converting an octahedral structure to a trigonal prismatic one at the TS are often associated with spin-state changes of the central metal atom enabled by spin−orbit coupling between different spin states.[141,142] However, in this work, we focus on the aspect of geometrical changes during the twisting motion.

In order to derive the appropriate curvilinear coordinates describing the two twist mechanisms, we first analyzed 15 normal modes for the AB_6 reference system with O_h symmetry (see Figure 47 in Appendix A.4) to search for one vibration that can best describe the twist motion about the C_3 axis in an octahedral geometry. However, we could not identify a single

vibration serving for this purpose. The only solution to obtain such a twist vibration turned out to equally mix the seventh, eighth, and ninth vibrations, which are triply degenerate normal modes describing q_2 puckering of four ligating atoms in a plane within the AB_6 reference system. The phase angles of parameter set $\{r_4, \theta_4, \phi_4\}$ describing the twisting motions have the following relationship:

$$|\cos \theta_m| = |\sin \theta_m \sin \phi_m| = |\sin \theta_m \cos \phi_m| \qquad (22)$$

There are in total eight sets of solutions to eq 22 in the spherical coordinate system. Four of them are listed in Table 6. The other four solutions are equivalent if the amplitude r_4 is multiplied by −1.

To illustrate how our curvilinear coordinates can be applied to study Bailar and Ray-Dutt twists, we selected a gallium(III) complex coordinated with three malondialdehyde ligands (see Figure 24) as an example, which was taken from a DFT study by Rzepa and Cass.[143] We pick this tris-chelate complex with Ga^{III} as the central atom instead of other transition metals (e.g., Sc^{III} and Ti^{III}) to avoid the complication from possible crossing of the PESs for two different spin states during the twist process.[43] These spin-crossings may be the reason why Rzepa and Cass[143] were unable the locate the TS for Bailar and Ray-Dutt twists of $Co^{III}(mda)_3$ on the singlet PES described with DFT.

The starting geometry of the core fragment of Λ-$Ga^{III}(mda)_3$ expressed in curvilinear coordinates is shown in Table 7.

4.3.1. Bailar Twist. For Λ-$Ga^{III}(mda)_3$, the Bailar twist corresponds to the second solution (i.e., $\theta_4 = 54.7°$, $\phi_4 = 135.0°$) of eq 22; see Table 6. However, the twist direction has to be anticlockwise to initiate this conformational change. From the data in Table 7, we learn that the curvilinear coordinates θ_4 and ϕ_4 of the reactant geometry are identical with those of the second solution; i.e., we can search for the aTS point of the Bailar twist simply via a relaxed PES scan for decreasing amplitude r_4, as shown in Figure 25.

The MEP starting from the refined TS structure shown in Figure 26 shows the conformational changes from Λ-$Ga^{III}(mda)_3$ to Δ-$Ga^{III}(mda)_3$ via a Bailar twist.

Concerning the geometrical changes in terms of curvilinear coordinates for the above Bailar twist process, one interesting observation is that the values of all phase angles (θ_m/ϕ_m) stay constant during the whole reaction path as in the reactant

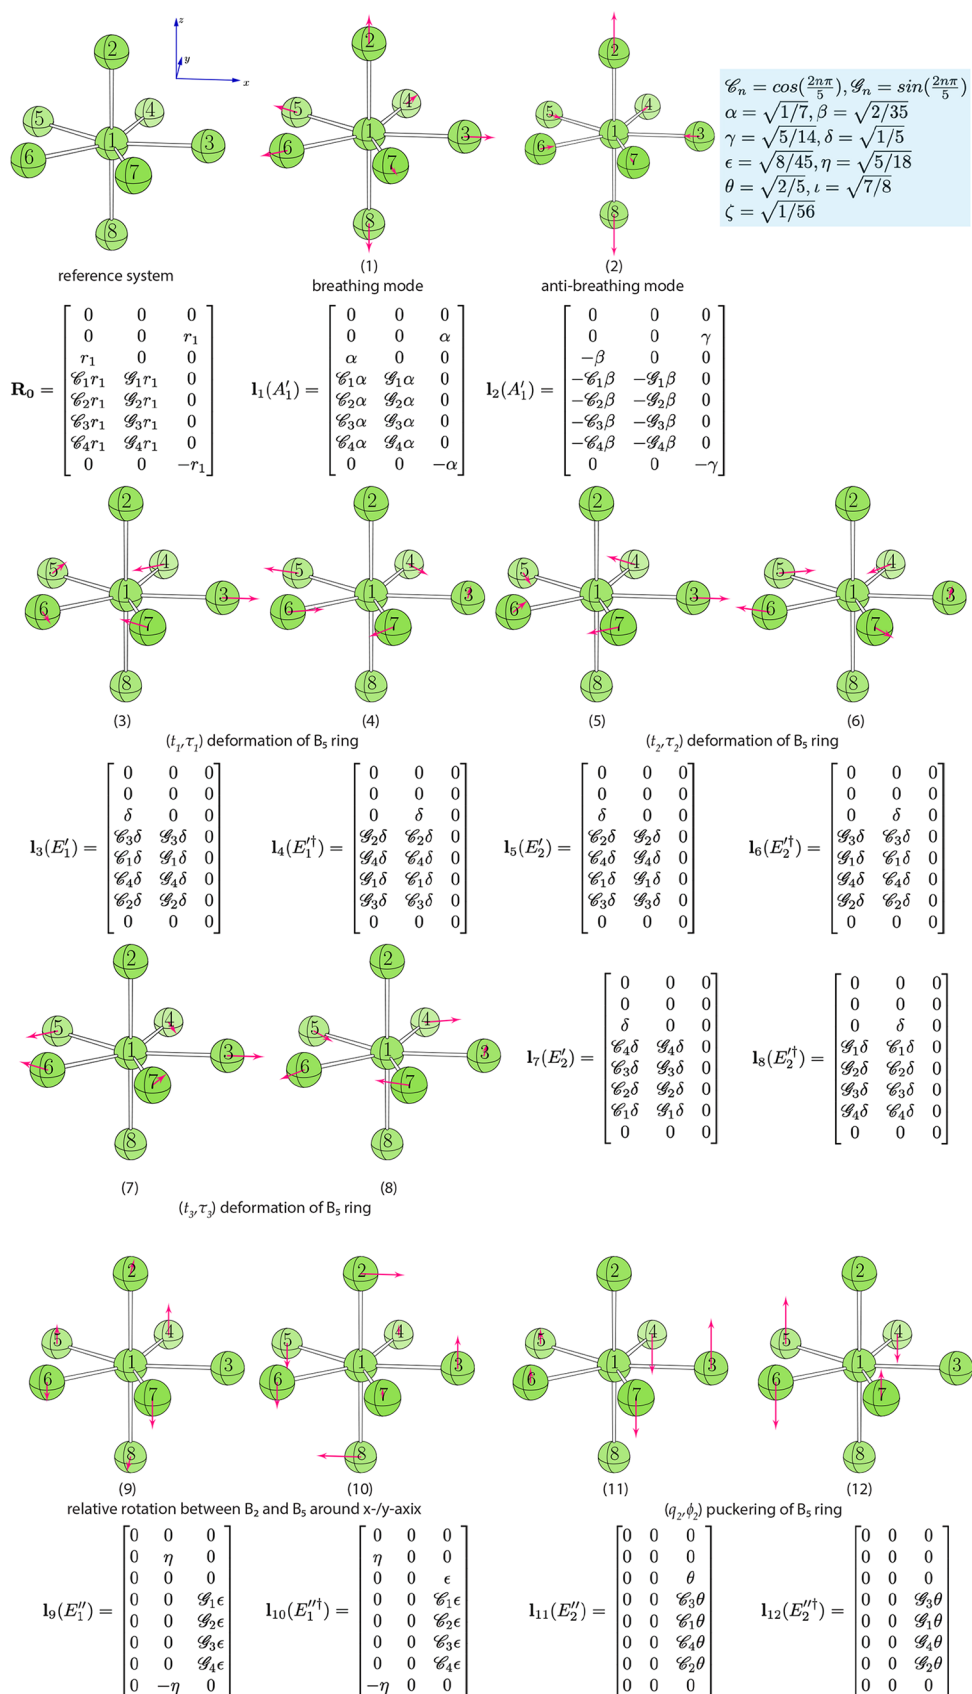

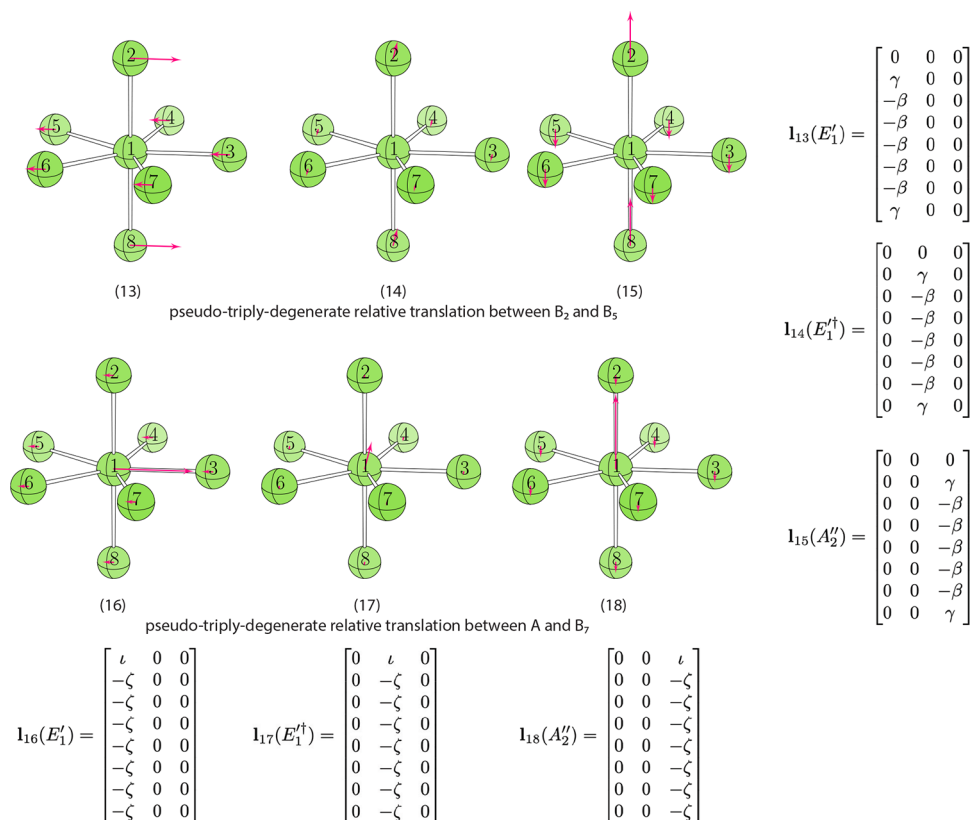

Figure 47. List of 18 normal vibrational modes for AB_7 reference system with D_{5h} symmetry. Below the ball-and-stick representations are the labels and brief descriptions of the normal modes. The irreducible representation and the mode vector for each vibration are also shown.

geometry. Figure 27 shows that among six amplitude r_m values, three of them stay as zero and the amplitude r_4 has the most significant change from 0.0 to −1.4 Å. We find that the values of the parameter set $\{r_3, \theta_3, \phi_3\}$ shown in Table 7 specify also an equal mixing of three degenerate normal vibrations (i.e., the fourth, fifth and sixth) of the octahedral AB_6 reference system. The joint effect of such combination leads to the synchronized change in the bite angles of three chelating ligands as revealed by the change in amplitude r_3 from 0.0 to 0.5 Å.

4.3.2. Ray-Dutt Twist. The Ray−Dutt twist in Λ-$Ga^{III}(mda)_3$ has three possible pathways as it has three pseudo-C_3 axes, which correspond to the first, third, and fourth solutions of eq 22 listed in Table 6. We selected the Ray−Dutt twist motion associated with the fourth solution to illustrate the use of curvilinear coordinates because ϕ_4 in the geometry of Λ-$Ga^{III}(mda)_3$ is the same as in the fourth solution, which simplifies the analysis. However, due to the D_3 symmetry in $Ga^{III}(mda)_3$, the choice from these three equivalent twists is in reality trivial.

When searching for the TS structure of the Ray−Dutt twist through a relaxed PES scan, we took a different route. Unlike for the other examples where the relaxed PES scans were carried out without any further constraint besides the driving coordinate variable, in this case we imposed one additional constraint, namely, $\theta_4 = 125.3°$ to properly orient the coordinate driving into the direction of Ray-Dutt twist. The change of θ_4 from 54.7° to 125.3° results in a marginal geometrical change for Λ-$Ga^{III}(mda)_3$ accompanied by an energy increase of less than 0.1 kcal/mol. By decreasing the amplitude r_4 stepwise, we successfully located the aTS point of the desired Ray-Dutt twist motion (see Figure 28).

After the refinement of the aTS geometry resulting in the TS, we mapped out the MEP of the Ray-Dutt twist, as shown in Figure 29.

Figure 30 shows that the amplitudes r_m behave in a similar way during Ray-Dutt twist as for the Bailar twist shown in Figure 27. This demonstrates the mechanistic similarity between Bailar and Ray-Dutt twists with regard to the motion of the core fragment.

Unlike the Bailar twist where four phase angles remain constant along the reaction path, only ϕ_4 is unchanged during Ray-Dutt twist. As shown in Figure 31, θ_3 drops to 54.7° and ϕ_3 increases to 225°. A discontinuity is found for θ_4 at $s = -8.5$ bohr as the amplitude r_4 equals zero at that point leading to no definition for θ_4 and ϕ_4 according to eq 16. However, this does not necessarily mean that the curvilinear coordinate system fails to describe a continuous conformational change along the reaction path, because the changes in amplitudes are still continuous.

4.4. Bartell Mechanism of Iodine Heptafluoride (IF_7). The IF_7 molecule is one of the most investigated prototypes of a heptacoordinated molecule,[144] and its fluxionality was first reported by Bartell and co-workers in the 1970s.[20,145,146] With its pentagonal bipyramidal molecular geometry in D_{5h} symmetry, the equatorial fluorine atoms can undergo a dynamic puckering motion inducing an axial bending leading to a pseudorotation path via a C_{2v} transition state. This polytopal rearrangement process was coined the *Bartell mechanism* for the first time by Minyaev and co-workers in 1994.[147] The transition path for the Bartell mechanism was modeled with quantum chemical calculations by Rzepa and co-workers in 2006.[15] Noteworthy is that Christe and co-workers proposed another much slower axial−equatorial ligand exchange mechanism for

IF_7 based on NMR evidence in 1993.[14] However, this process seemed to be too complicated and was never confirmed afterward.

In this work, we focused on the Bartell mechanism being described with our curvilinear coordinates. The optimized geometry of IF_7 molecule is described in Table 8, where three phase angles ϕ_m associated with $r_m = 0$ was intentionally set to 180°.

As described in Bartell's original work, this pseudorotation path is dominated by E_2'' puckering.[20] Analyzing the vibration library data of the reference system (see Appendix A.5) we found that the parameter set $\{r_7, \phi_7\}$ corresponds to doubly degenerate (q_2, ϕ_2) ring puckering vibrations. By carrying out a relaxed PES scan with the increasing amplitude r_7, we successfully located the aTS point for the Bartell mechanism, as shown in Figure 32.

After refinement of the TS point, the complete MEP was mapped out, as shown in Figure 33 revealing the Bartell mechanism. The changes in amplitudes r_m and phase angles θ_m/ϕ_m of IF_7 along the MEP are shown in Figures 34 and 35.

Along the MEP, amplitudes r_2 through r_8 are increased to different extent. The amplitude r_9 adopts the zero value throughout the whole path and its associated phase angles are thus not shown. Similar to several other dynamic fluxional processes discussed above, the phase angles also adopt constant values along the whole reaction path. Amplitude r_7 has the largest increase from 0.0 to 0.7 Å, followed by the amplitude r_8 from 0.0 to 0.6 Å. Phase angle ϕ_7 takes the value of 162°, indicating a dominant contribution from the 11th normal mode (cos $\phi_7 = -0.95$) compared with the 12th normal mode (sin $\phi_7 = 0.31$). For the parameter set $\{r_8, \theta_8, \phi_8\}$, θ_8 is 145° and ϕ_8 equals 90°, which specifies the mixing of the 13th and 14th vibrational modes without any contribution from the 15th normal mode, leading to an axial bending motion. In summary, the conformational changes described in terms of curvilinear coordinates are consistent with Bartell's original description of distortion from D_{5h} symmetry for IF_7.[20]

4.5. Two Technically Complicated Fluxional Mechanisms.
In the above examples illustrating the usefulness of our newly developed curvilinear coordinate system for the description of dynamic fluxional processes, we have demonstrated that the search of the aTS point for the polytopal rearrangement processes can be done in a systematic way via a relaxed PES scan starting from equilibrium geometry using a single amplitude r_m from the complete set of curvilinear coordinates as a variable.

In the following, we discuss two examples for which the single-parameter PES scan protocol fails to locate the aTS point and we present a solution for successfully finding the aTS point in these cases. Rather than undermining the value of the curvilinear coordinates developed in this work, these two examples reflect robustness and flexibility of our approach.

4.5.1. Chimeric Pseudorotation of Iodine Pentafluoride (IF₅).
Similar to IF_7, the iodine pentafluoride (IF_5) is also a hypervalent halogen compound. Its square pyramidal (C_{4v}) geometry was first reported by Lord and co-workers in 1950.[148] Several years later in 1957, Muetterties and Phillips carried out ^{19}F NMR studies on IF_5, and they observed IF_5 being stable at room temperature. However, the absence of F−F coupling pattern in NMR spectra at elevated temperatures indicated apical-basal fluorine exchange.[121] Therefore, they concluded that such apical-basal exchange has a relatively high energy barrier over 25 kcal/mol and they hypothesized that this process would proceed via a dimer structure. During the following years,

little progress was made with regard to a more detailed understanding of the fluxional mechanism of IF_5 until in 2006 when Rzepa and Cass suggested a nondissociative (i.e., intramolecular) mechanism based on quantum chemical calculations.[25] Their reaction path analysis led to the conclusion that the fluxional mechanism of IF_5 is composed of three distinct fluxional processes mixed together, which they coined *chimeric pseudorotation*. Noteworthy is that the BrF_5 can undergo the same chimeric pseudorotation as IF_5 via a C_s TS according to Rzepa's calculations, while the ClF_5 adopts a different path via a C_{2v} TS resembling a Berry pseudorotation, which was exemplified by PF_5, SF_4, and $Fe(CO)_5$, as discussed above. In this work, we studied the chimeric pseudorotation of IF_5 with curvilinear coordinates to further explore Rzepa's findings. Equilibrium geometry data of IF_5 are collected in Table 9.

In order to locate the aTS point for the chimeric pseudorotation mechanism, we performed a relaxed PES scan of a single amplitude parameter using r_3 through r_7, one at a time combined with various phase angle possibilities, but failed to capture the desired aTS point. After closer inspection of the IF_5 equilibrium geometry compared with the TS geometry calculated by Rzepa,[25] we found that the geometrical change from reactant toward TS can be attributed to a q_2 puckering motion of four basal fluorines combined with a (t_1, τ_1) deformation of the same four-membered ring. According to the vibration library for the AB_5 reference system in C_{4v} symmetry (see Figure 3), the displacement of q_2 puckering and (t_1, τ_1) deformation for the B_4 ring is controlled by r_3 and $\{r_4, \phi_4\}$, respectively. Therefore, we performed next a 2D relaxed PES scan of r_3 and r_4, as shown in Figure 36, and the aTS point could be correctly identified.

After the refinement of the TS point, the complete MEP of the chimeric pseudorotation for IF_5 was mapped out as shown in Figure 37.

The change in the amplitude values along the MEP shown in Figure 38 is rather simple as r_3 through r_6 all increase from 0.0 Å in the very beginning. Noteworthy is that r_3 and r_4 stay close to each other and progress in a synchronized fashion. The phase angle change in Figure 39 shows ϕ_4 gradually increases from 60.0° to 85.0°, indicating more contribution from the fifth normal mode than the fourth.

For this showcase example, one might suggest combining the third normal mode from the vibrational library with the fourth and fifth modes forming a pseudotriply degenerate curvilinear coordinate parameter set, as these three vibrational modes are highly similar and in this way allowing to locate the aTS point via a single-parameter (i.e., amplitude) relaxed PES scan, which is simpler than 2D scan. It is feasible to implement the curvilinear coordinates in that way. However, the grouping of the vibrations with different symmetries into either pairs or triads is not arbitrary. We rather prefer to group vibrations depending on their types of motion. The third vibration is the puckering motion of the four-membered ring of the basal F atoms, while the fourth and fifth vibrations are related to ring deformation. Separating these two well-defined motions is physically more meaningful.

4.5.2. Lever Mechanism of Sulfur Tetrafluoride (SF₄).
In addition to the Berry pseudorotation of SF_4 discussed in section 4.1, other mechanisms were proposed to enable complete scrambling of its four fluorine atoms.[149] The most credible alternative to Berry pseudorotation, termed *lever mechanism*, was first proposed by Minyaev and co-workers[147] and further

investigated by Mauksch and Schleyer with theoretical calculations.[17]

We failed to locate the aTS point pertaining to the lever mechanism in SF_4 with curvilinear coordinates via a relaxed PES scan of either one single amplitude or two amplitudes, as we did for IF_5. The correct aTS point was successfully disclosed by a relaxed PES scan of the two phase angles of the parameter set $\{r_4, \theta_4, \phi_4\}$, which corresponds to relative translations of the central atom.

As shown in the right half of the energy contour plot in Figure 40, there are three reaction valleys interconnected with each other by three first-order saddle points. The green round dot in the upper reaction valley corresponds to the reactant geometry for SF_4 described in Table 2. In the middle of three first-order saddle points, there is a second-order saddle point corresponding to a C_{3v} geometry[17] with slightly higher energy (~1.0 kcal/mol). The left region of this contour map seems to be centrally symmetric to the right part.

Our results are consistent with the qualitative energy landscape of Mauksch and Schleyer, which led them to the conclusion that three MEPs of lever mechanism encircle the second-order saddle point.[17] They named such an energy surface where three valleys meet on a hilltop having two imaginary frequencies[150,151] as "effective monkey saddle point", which has to be distinguished from an ideal "monkey saddle" where doubly degenerate zero curvatures are required.[152,153] In this sense, we have now consolidated the work of Mauksch and Schleyer[17] for the first time by presenting a detailed description of the unusual PES of the SF_4 lever mechanism with the help of our new curvilinear coordinates.

On the basis of a refined TS point, the MEP marked out in the above 2D PES contour plot was mapped out in Figure 41.

The conformational change of SF_4 expressed in curvilinear coordinates during the lever pseudorotation is shown in Figures 42 and 43.

The amplitude values along the MEP are symmetric with regard to $s = 0$ bohr. Amplitude r_4 has the least change although its associated phase angles θ_4 and ϕ_4 play a central role in driving the reaction coordinates.

Among all phase angles, θ_4 and ϕ_4 show a moderate change along the reaction path. Throughout the whole path these two phase angles change from 90° and 360° toward 135° and 270°, respectively, specifying the full contribution from the ninth normal vibration ($\sin \theta \cos \phi = 1$) for the reactant geometry and equal contributions from the seventh and eighth normal modes ($\cos \theta = \sin \theta \sin \phi = -\sqrt{2}/2$) for the product geometry. This means that the reactant geometry is basically a result of the upward translation of the central sulfur atom in the $+z$ direction. With the progress of lever mechanism the contribution of this upward translation decays (i.e., central sulfur moves downward) and the sulfur atom gradually moves into the $-x$ and $-y$ direction.

A similar variation is also found for θ_3 and ϕ_3. On the basis of this observation, we performed a relaxed PES scan of these two phase angles in order to locate the aTS point. However, it turned out that the only solution leading to the correct aTS point is via relaxed scanning of θ_4 and ϕ_4.

5. CONCLUSIONS

We developed in this work a novel curvilinear coordinate system describing polytopal rearrangements in N-coordinate compounds, where N can take any number from four through seven:

(1) The physical foundation of this curvilinear coordinate system is based on the fact that a chemical reaction can be initiated and even accelerated via the excitation of vibrational modes of the reaction complex.[68−70,74,75] The polytopal rearrangements in N-coordinate molecules, like conformational changes, can be considered as unimolecular reactions, which are amenable to the promotion by certain vibrations. In this sense, the new curvilinear coordinate system is a conceptual extension of the Cremer−Pople ring puckering coordinates[47] as well as the recently proposed ring deformation coordinates.[54]

(2) The curvilinear coordinates developed in this work are derived from the normal vibrational modes of N-coordinate reference systems AB_n, for which $3M − 6$ curvilinear coordinates (where $M = N + 1$) are sufficient to describe the geometry of any N-coordinate motif.

(3) A reference system AB_n defines a geometrical template (i.e., its size is scalable) with a highly symmetric N-coordinate structure that fulfill several preconditions. In this work, we have stipulated reference systems for different N-coordinate structures ranging from tetracoordinate to heptacoordinate in different point groups including AB_4 in T_d symmetry, AB_5 in D_{3h} and C_{4v} symmetries, AB_6 in O_h and C_{5v} symmetries along with AB_7 in D_{5h} and C_{6v} symmetries. These reference systems cover the vast majority of single-center coordination compounds (versus binuclear and polynuclear complexes).

(4) In a coordination compound, the geometry of its N-coordinate core fragment ("real system") can be unambiguously expressed by the nonredundant set of $3M − 6$ normal vibrations of corresponding reference system AB_n if the internal coordinate space of the real system matches exactly the internal vibration space of the reference system. This is realized by translating and rotating the real system into a standard orientation, from which the geometrical information is encoded by the projection of Cartesian coordinates onto the $3M − 6$ normal vibrations of the reference system. Depending on the degeneracy and type of motion of the $3M − 6$ normal vibrational modes, some of the $3M − 6$ projections are grouped into pairs or triads, leading to three kinds of curvilinear coordinate parameter sets: (i) non-degenerate $\{r_m\}$, (ii) doubly degenerate $\{r_m, \phi_m\}$, and (iii) triply degenerate $\{r_m, \theta_m, \phi_m\}$. The latter two parameter sets with phase angles (θ_m/ϕ_m) linearly combine two and three vibrations, respectively.

(5) Any complete set of internal or Cartesian coordinates of an N-coordinate structure can be transformed into $3M − 6$ curvilinear coordinates. In turn, the curvilinear coordinates can be used to derive the internal or Cartesian coordinates of the N-coordinate structure.

(6) The new curvilinear coordinates are well-suited reaction coordinates for describing polytopal rearrangements in two aspects. First, these curvilinear coordinates can directly be used for 1D/2D relaxed PES scan starting from an equilibrium geometry to locate the first-order saddle point (TS). In most cases, the equilibrium geometry of the reactant is close to that of the corresponding reference system with many amplitude parameters r_m being almost zero (except r_1). A relaxed PES scan in which one or two amplitudes r_m are steadily increased simulates the process of the vibration(s) (associated with the scanned amplitudes) being excited to obtain pronounced atomic displacements. Noteworthy is that, like using internal coordinates for relaxed PES scans, the choice of curvilinear coordinations as the constraint variables requires them to be closely related to the vibrations initiating a polytopal rearrangement process. Even in the rare case that the molecular geometry

is different from its best suited reference system in terms of symmetry (e.g., SF_4 with C_{2v} symmetry versus its reference system with T_d symmtry), a relaxed PES scan with our curvilinear coordinate system can reveal important mechanistic details. Second, the polytopal rearrangement pathways (especially in the entrance channel before TS) can be better understood in terms of one or two leading vibrational motions. Such a simplification has been widely used in understanding the conformational change of proteins.[154]

(7) Nine different polytopal rearrangement processes in tetracoordinate through heptacoordinate compounds were studied, including the Berry pseudorotation and the lever mechanism for SF_4, the chimeric pseudorotation for IF_5, the Berry pseudorotation and the Muetterties' mechanisms for trigonal bipyramidal structures, Bailar and Ray-Dutt twists for tris-chelates, and the Bartell mechanism for IF_7. These showcase examples endorse the general applicability of our curvilinear coordinates for the description of polytopal rearrangements for different coordination structures.

Noteworthy is that in the case of several polytopal rearrangement mechanisms studied in this work, the phase angles (θ_m/ϕ_m) are unchanged along the whole pathway, including the Berry pseudorotations for SF_4 and $Fe(CO)_5$, the Bailar twist for tris-chelates and the Bartell mechanism for IF_7. This finding is closely related to the observation of Avnir, Alvarez, and co-workers that the Berry pseudorotation in pentacoordinate compounds and the Bailar twist possess minimal distortion pathways according to their CShM analysis.[23]

On the basis of the curvilinear coordinate framework introduced in this work, work in progress covers the following directions:

- The curvilinear coordinates will be employed to explore all possible polytopal rearrangement mechanisms for newly discovered and intriguing coordination structures.

- Unconfirmed polytopal mechanisms reported in the literature will be revisited, like the chimeric pseudorotation for IF_5 rediscovered and studied by Rzepa and Cass.[25]

- More reference systems and associated curvilinear coordinates are to be designed for heptacoordinate and octacoordinate compounds, which are less explored compared with lower coordinated counterparts in the hope of discovering novel polytopal rearrangement mechanisms.

- The curvilinear coordinate system can be incorporated into automatic workflows for high-throughput screening for polypotal rearrangements as well as rational design of transition-metal complexes. Related work in this direction has been pioneered by the Kulik group.[155−158]

- Collective variables based on the curvilinear coordinates developed in this work will be implemented in order to sample free energy surfaces of polytopal rearrangements with molecular dynamics simulations.[159]

In conclusion, this work introduces a dedicated curvilinear coordinate system for the description of polytopal rearrangements in coordination compounds opening a new avenue for the systematic study and comparison of these fluxional processes.

■ APPENDIX A

A.1. Formula for Wilson B- and dB-Matrix

We have derived the formulas to calculate the Wilson **B**-matrix and its derivative for the curvilinear coordinate system developed in this work using finite difference method.

(i) Nondegenerate curvilinear coordinate $\{r_m\}$

$$\frac{\partial r_m}{\partial x_i} = \mathcal{F}\frac{\Delta d_m}{\Delta x_i} \tag{23}$$

$$\frac{\partial^2 r_m}{\partial x_i \partial x_j} = \mathcal{F}\frac{\Delta^2 d_m}{\Delta x_i \Delta x_j} \tag{24}$$

(ii) Doubly degenerate curvilinear coordinates $\{r_m, \phi_m\}$

$$\frac{\partial r_m}{\partial x_i} = \mathcal{F}\left(\cos \phi_m \frac{\Delta d_m}{\Delta x_i} + \sin\phi_m \frac{\Delta d'_m}{\Delta x_i}\right) \tag{25}$$

$$\frac{\partial \phi_m}{\partial x_i} = \frac{\mathcal{F}}{r_m}\left(-\sin\phi_m \frac{\Delta d_m}{\Delta x_i} + \cos \phi_m \frac{\Delta d'_m}{\Delta x_i}\right) \tag{26}$$

$$\frac{\partial^2 r_m}{\partial x_i \partial x_j} = \mathcal{F}\left(\cos \phi_m \frac{\Delta^2 d_m}{\Delta x_i \Delta x_j} + \sin \phi_m \frac{\Delta^2 d'_m}{\Delta x_i \Delta x_j}\right) + r_m \frac{\Delta \phi_m}{\Delta x_i} \frac{\Delta \phi_m}{\Delta x_j} \tag{27}$$

$$\frac{\partial^2 \phi_m}{\partial x_i \partial x_j} = \frac{\mathcal{F}}{r_m}\left(-\sin \phi_m \frac{\Delta^2 d_m}{\Delta x_i \Delta x_j} + \cos \phi_m \frac{\Delta^2 d'_m}{\Delta x_i \Delta x_j}\right) - \frac{1}{r_m}\left(\frac{\Delta r_m}{\Delta x_i} \frac{\Delta \phi_m}{\Delta x_j} + \frac{\Delta r_m}{\Delta x_j} \frac{\Delta \phi_m}{\Delta x_i}\right) \tag{28}$$

(iii) Triply degenerate curvilinear coordinates $\{r_m, \theta_m, \phi_m\}$

$$\frac{\partial r_m}{\partial x_i} = \mathcal{F}\left(\cos \theta_m \frac{\Delta d_m}{\Delta x_i} + \sin \theta_m \sin \phi_m \frac{\Delta d'_m}{\Delta x_i} + \sin \theta_m \cos \phi_m \frac{\Delta d''_m}{\Delta x_i}\right) \tag{29}$$

$$\frac{\partial \theta_m}{\partial x_i} = \frac{\mathcal{F}}{r_m}\left(-\sin \theta_m \frac{\Delta d_m}{\Delta x_i} + \cos \theta_m \sin \phi_m \frac{\Delta d'_m}{\Delta x_i} + \cos \theta_m \cos \phi_m \frac{\Delta d''_m}{\Delta x_i}\right) \tag{30}$$

$$\frac{\partial \phi_m}{\partial x_i} = \frac{\mathcal{F}}{r_m \sin \theta_m}\left(\cos \phi_m \frac{\Delta d'_m}{\Delta x_i} - \sin \phi_m \frac{\Delta d''_m}{\Delta x_i}\right) \tag{31}$$

$$\frac{\partial^2 r_m}{\partial x_i \partial x_j} = \mathcal{F}\left(\cos \theta_m \frac{\Delta^2 d_m}{\Delta x_i \Delta x_j} + \sin \theta_m \sin \phi_m \frac{\Delta^2 d'_m}{\Delta x_i \Delta x_j} + \sin \theta_m \cos \phi_m \frac{\Delta^2 d''_m}{\Delta x_i \Delta x_j}\right) + r_m \frac{\Delta \theta_m}{\Delta x_i} \frac{\Delta \theta_m}{\Delta x_j} + r_m \sin^2 \theta_m \frac{\Delta \phi_m}{\Delta x_i} \frac{\Delta \phi_m}{\Delta x_j} \tag{32}$$

$$\frac{\partial^2 \theta_m}{\partial x_i \partial x_j} = \frac{\mathcal{F}}{r_m}\left(-\sin\theta_m \frac{\Delta^2 d_m}{\Delta x_i \Delta x_j} + \cos\theta_m \sin\phi_m \frac{\Delta^2 d_m'}{\Delta x_i \Delta x_j}\right.$$
$$\left. + \cos\theta_m \cos\phi_m \frac{\Delta^2 d_m''}{\Delta x_i \Delta x_j}\right)$$
$$- \frac{1}{r_m}\left(\frac{\Delta r_m}{\Delta x_i}\frac{\Delta\theta_m}{\Delta x_j} + \frac{\Delta r_m}{\Delta x_j}\frac{\Delta\theta_m}{\Delta x_i}\right)$$
$$+ \sin\theta_m \cos\theta_m \frac{\Delta\phi_m}{\Delta x_i}\frac{\Delta\phi_m}{\Delta x_j} \tag{33}$$

$$\frac{\partial^2 \phi_m}{\partial x_i \partial x_j} = \frac{\mathcal{F}}{r_m \sin\theta_m}\left(\cos\phi_m \frac{\Delta^2 d_m'}{\Delta x_i \Delta x_j} - \sin\phi_m \frac{\Delta^2 d_m''}{\Delta x_i \Delta x_j}\right)$$
$$- \frac{1}{r_m}\left(\frac{\Delta r_m}{\Delta x_i}\frac{\Delta\phi_m}{\Delta x_j} + \frac{\Delta r_m}{\Delta x_j}\frac{\Delta\phi_m}{\Delta x_i}\right)$$
$$- \frac{1}{\tan\theta_m}\left(\frac{\Delta\theta_m}{\Delta x_i}\frac{\Delta\phi_m}{\Delta x_j} + \frac{\Delta\theta_m}{\Delta x_j}\frac{\Delta\phi_m}{\Delta x_i}\right) \tag{34}$$
